Pulmonary Effects. The major concern in cobalt toxicology are pulmonary diseases caused by inhalation of cobalt and cobalt compounds, as occurs in the production and processing of cobalt and cobalt compounds and in the production of hard metals composed of cobalt and tungsten carbide. The symptoms include decreased pulmonary function, asthma, inflammation, and ultimately lung carcinoma [30, 31, 33]. For the nonmalignant pulmonary effects, the U.S. Agency for Toxic Substances and Disease Registry has estimated a LOAEL (lowest observed adverse effect level) of 0.0151 mg Co/m^3 and a NOAEL (no observed adverse effect level) of 0.0053 mg Co/m^3 [30].

Carcinogenicity. Few epidemiological studies on cohorts of cobalt-exposed workers have been performed. They showed some evidence for lung carcinogenicity of cobalt and cobalt compounds [31, 34]. However, no firm conclu-

sions about the human carcinogenicity of cobalt and cobalt compounds can be drawn because of small numbers, limited statistical confidence, and co-exposure to other metals. Studies on workers employed in the production of hard metals revealed a significant correlation between exposure and incidence of lung cancer [33]. In experimental inhalation studies with both rats and mice, cobaltous sulfate evoked the formation of lung tumors [35].

Table 24. Classification of cobalt and cobalt compounds as carcinogens [30], [31], [33], [34]

Agency	Substances	Classification
IARC 1990 [31]	cobalt and cobalt compounds	2B (possibly carcinogenic to humans)
EU 2004	cobalt dichloride	2 (considered to be carcinogenic for humans)
	cobalt sulfate	2 (considered to be carcinogenic for humans)
DFG 2001 [34]	cobalt and cobalt compounds	2 (considered to be carcinogenic for humans)
DFG 2004 [33]	hard metal, composed of tungsten carbide and cobalt	1 (causes cancer in humans)
Germany 2004	cobalt (elemental)	3 (possibly carcinogenic to humans)
	soluble cobaltous salts	2 (considered to be carcinogenic for humans)
	cobalt oxide and cobalt sulfide	3 (possibly carcinogenic to humans)
ACGIH 2003	cobalt, elemental and inorganic compounds	A3 (confirmed animal carcinogen with unknown relevance to humans)

The epidemiological and animal data are supported by mechanistic studies in vitro which reveal that cobalt compounds are weakly genotoxic but that cobalt enhances the genotoxicity of other agents because it inhibits the repair of damaged DNA [34]. Furthermore, the genotoxicity of cobalt-containing hard metals is severalfold higher than the genotoxicity of the cobalt component alone. This enhancing effect is attributed to a catalytic role of tungsten carbide in the formation of reactive oxygen species [30, 33].

Reproductive Toxicity. There are no data about the reproductive toxicity of cobalt in humans. In experiments with male mice, high oral doses of $CoCl_2$ caused reduced sperm count, testes weight, and fertility [30, 34]. After mating of treated males with untreated females, embryonic losses were registered. Also with male rats, oral administration of $CoCl_2$ caused degeneration and necrosis of the testes and reduced spermatogenesis [30, 34].

Environmental Toxicity. There are little data about the environmental toxicity of cobalt and cobalt compounds in microorganisms, plants, and animals except farm animals. Accidental feeding of several grams of cobalt to sheep have caused fatalities [29]. Extrapolating from experimental data, it is probable that the levels of cobalt encountered in the environment do not exert significant toxicity on environmental species. Of course, this conclusion does not apply to biological effects of effluents and waste dumping sites of metal industries.

Regulations and Guidelines. The qualitative classification of cobalt and cobalt compounds with respect to carcinogenicity is summarized in Table 24. Whereas previously some regulatory agencies have classified cobalt and its compounds as a whole group, recent classifications tend to classify cobalt compounds individually according to the degree of evidence for carcinogenicity to humans. Table 25 summarizes quantitative toxicity and limit values issued by various agencies. This table reveals considerable differences in quantitative risk estimation between agencies of different countries. Obviously, there is a lack of data with respect to quantitative effect – exposure relations and a need for harmonization of regulations in the future.

Table 25. Synopsis of limit values for cobalt and cobalt compounds (as elemental cobalt).

Description	Limit values	Source
Occupational limit values for Cobalt and inorganic compounds	0.5 mg/m^3 TELa	Germany 2004
	0.1 mg/m^3 TELb	Germany 2004
	0.1 mg/m^3 PELc	OSHA 2003
	0.05 mg/m^3 RELd	NIOSH 2001
	0.02 mg/m^3 TLVe	ACGIH 2000
Occupational biological exposure equivalent for cobalt and its compounds	25 µg/L in blooda300 µg/L in urinea	Germany 2004
	5 µg/L in bloodb60 µg/L in urineb	Germany 2004
Occupational biological exposure index for cobalt and its compounds	15 µg/L in urine	ACGIH 2000
	1 µg/L in blood, both at end of shift at end of work week	ACGIH 2000
Food. Cobaltous salts and their derivatives	Prohibited from use in human food	FDA 2000

a Technical exposure limit, production of cobalt powder, catalysts, hard metals, magnets.
b Technical exposure limit, all other processes.
c Permissible exposure limit.
d Recommended exposure limit.
e Threshold limit value.

1. Introduction [1 – 3]

Commercial coffee, the dried seed from two species of the genus *Coffea, C. arabica* and *C. robusta,* is grown as a short tree in the tropics at an altitude ranging from sea level to more than 2000 m. The ripe cherries (sometimes incorrectly called "berries"), which usually contain two seeds – the coffee beans – are harvested and processed in one of two ways.

In the *dry process*, the cherries are dried in the sun for a period of up to three weeks, and the outer and inner shells are mechanically removed to liberate the coffee beans ("green coffee"), which can be cleaned and bagged. This method is usually applied to Arabicas from Brazil, the main coffee-producing country, and Ethiopia, as well as to all Robustas, of which Indonesia and Vietnam are the main producers.

In the *wet process*, the outer skin of the cherry is squeezed through slots and the pulp surrounding the beans is fermented and washed away. The beans, still covered by the inner shell, the parchment, are dried either for a period of up to 1 week in the sun or for a shorter period in a dryer. After mechanical removal of the parchment, the beans are cleaned and bagged. The main producer of wet-processed Arabicas, sold as "mild coffees" or "milds", is Colombia, followed by the Central American and Eastern African countries.

Europe, North America, and Japan are the main consumers. Of the producing countries, Brazil is the main consumer. For consumption, coffee is roasted (and ground) for sale and consumed as a brew, or further treated by extraction, concentration, and spray- or freeze-drying and sold as soluble (instant) coffee.

Caffeine, the active principle of coffee, can be removed from the green bean after soaking in water, by dissolving it in a solvent, such as dichloromethane, ethyl acetate, or supercritical carbon dioxide. Adsorption on activated carbon is also employed. In addition to caffeine, ca. 1 % in Arabicas and 2 % in Robustas, the dry bean contains ca. 50 % carbohydrates, 8–17 % lipids, up to 11 % proteins and amino acids, and ca. 5 % minerals. During roasting, these components form the typical coffee flavor, of which more than 1000 components, many of them fragrant or sapid, have been identified.

2. History [4]

Unlike most cultivated plants whose primitive strains have long ago disappeared by genetic erosion, wild coffee plants, related to the actual cultivars of *C. arabica*, still exist in East Africa in the region where the main species originated. The plant spread from the rainy forests around Lake Victoria to the Kaffa province in the Ethiopian highlands, north to the arid Sudan, where its sweet red cherries, *bunna*, were picked and chewed. Dried cherries are easily stored and transported; thus, their use reached the coastal area, where they are known as *m'buni* or *buni*, and are still consumed sweetened and unroasted on special occasions as a ceremonial food.

Intense commercial and political exchanges across the Red Sea introduced coffee use to Arabia, and its culture may have started as early as the sixth century in the fertile valleys of the country now known as Yemen.

The advent of Mohammedanism, forbidding the use of alcoholic beverages and encouraging exchanges through pilgrimages to Mecca, together with the flourishing of the Arabian and Persian civilizations, asserted the strength of coffee around the harbor of Mocha and its extension eastward. The Persian scholars Rhazes (850–922) and Avicenna (980–1037) mention the digestive properties of coffee, probably identified with *bunchum* by the former and called *bon* or *ban* by the latter.

According to Abdelkadir, who in 1587 wrote the first historical account dealing specifically with coffee, the expansion northward appears to have been slower. It was only by the second half of the 15th century that coffee, which was then being roasted and consumed as a brew, *kahwa*, had conquered the whole Arabian peninsula and reached the Mediterranean Sea. During the 16th century, coffee became very popular throughout the Ottoman Empire.

The stimulating properties of coffee are described by the legends reported in Abdelkadir's manuscript, where strength to survive in the desert or to stay awake and pray is restored to holy people by chewing the sweet berries or by drinking a beverage prepared by roasting the berries to make them softer and to reduce their bitterness. Leonhard Rauwolf (ca. 1540–1596), physician and botanist from Augsburg, was one of the first Europeans to describe coffee as a drink "almost as black as ink" and to give a vivid description of Aleppo's coffeehouses. Prospero Alpini (1553–1617), physician and professor of botany at the University of Padua, drew the first picture of a coffee branch from a tree seen in the garden of the Bey in Cairo. By way of Venice, coffee from Mocha conquered Europe in the 17th century. Coffee culture was introduced to the Malabar coast of India and to Ceylon toward the turn of the 16th century. By the end of the 17th century the Dutch had succeeded in cultivating coffee on a commercial basis in Java; they broke the Mocha monopoly in 1711, when the first coffee produced in the East Indies was auctioned in Amsterdam. Seedlings from a plant brought to Amsterdam in 1706 were distributed to the European botanical gardens. Due to a state of war, the French waited until 1713, when a plant 5 ft (ca. 2 m) tall was sent to Louis XIV, the Sun King. It was planted in the Jardin des Plantes in Paris and described by Antoine de Jussieu. By royal bequest it became the ancestor, with related plants from Amsterdam, of most of the coffee trees planted during the 18th century in the Western hemisphere, which eventually led to the decay of Dutch supremacy in the trading of coffee.

The Swedish botanist Linnaeus, a friend of the Jussieu family, classified the plant as *Coffea arabica* in 1753. Caffeine [*58-08-2*], the active ingredient of coffee, was isolated by Runge in 1820 from a few beans received from Goethe. The formula of caffeine, which had been determined from combustion data by Pfaff and Liebig in 1832, was established by Medicus in 1875 as 1,3,7-trimethylxanthine, $C_8H_{10}N_4O_2$,

M_r 194.19, and confirmed by E. Fischer in 1897 by total synthesis.

Caffeine (1,3,7-trimethylxanthine)

The year 1869 saw the destruction of coffee culture in Ceylon (Sri Lanka) by the fungus *Hemileia vastatrix* (coffee rust) and the spread of infection to the low-altitude plantations in India, Java, and Sumatra. The Dutch botanist Pierre studied the sources of coffee and in 1895 found a rust-resistant species in Congo, *Coffea canephora,* var. *robusta*, now the second most economically important type of coffee. Roselius, a Bremen coffee merchant, devised the technique of steaming coffee beans to enlarge their pores, then washing out the caffeine with a solvent. A patent was issued in 1906 for the decaffeination of green coffee beans by a technique very similar to those applied currently.

From the beginning of the 20th century on, coffee cooking ceased to be considered a plain kitchen task and stimulated the ingenuity of inventors that produced a range of increasingly sophisticated and complex brewing devices. From the first steam kettle patented in 1901 to the lever-operated and the electrical pump-driven machines, this effort culminated with the present-day computer-controlled "espresso" machines.

For the sake of convenience, instantly soluble coffee has gained nowadays a wide diffusion. A patent for making instant coffee had already been granted to Gale in 1865, and commercial soluble coffee made its faint appearance at the beginning of the 20th century. It was not until 1938 that Morgenthaler succeeded in obtaining the first 19 t of a free-flowing, stable, and readily soluble coffee extract, which the United States army found to be very convenient during World War II. Pure coffee extract was introduced in 1950, and in 1964 freeze-dried granules appeared on the market, having a flavor that approached that of brew. The introduction of vacuum packing and the developments of home brewers have, in the 1980s and 1990s, brought roast and ground coffee to a level of convenience approaching that of soluble coffee.

3. Green (Raw) Coffee

3.1. Botany and Culture [5 – 7]

The genus *Coffea* L. (Rubiaceae) consists of about 100 species classed as *eucoffea*. The subgenera *erythrocoffea*, which contains all of the cultivated species, and *argocoffea* are both native to continental Africa. *Mascarocoffea* from Madagascar and *paracoffea* from the Indian subcontinent are low in caffeine. Two species only are economically important, both cultivated around the world in the tropical belt, *Coffea arabica* L., Arabica coffee, with two main varieties, *bourbon* and *typica*, accounting for two-thirds of world production, and *Coffea canephora* Pierre, one main variety *robusta*, one-third of world production (Table 1). Two other species, *C. liberica* Bull ex Hiern, Liberica coffee, and *C. dewevrey* De Wild., Excelsa coffee, have lost all commercial importance. Arabica cultivars have been developed for visual characteristics, such as "maragogype", a mutant from *typica* producing giant beans; productivity, such as "Mundo Novo" in Brazil; or resistance to diseases, like "Ruiru eleven" in Kenya, resistant to the coffee berry disease, but which has lost some of the typical flavor of Kenyan coffee.

The genetic variability of Arabica coffee has remained until quite recently extremely limited; as a consequence, susceptibility to two fungal diseases, coffee leaf rust (CLR), caused by *Hemileia vastatrix*, now encountered worldwide at low altitudes, and coffee berry disease (CBD), produced by *Colletotrichum kahawae*, previously known as *C. caffeanum*, which attacks the green and ripening fruits in cool areas at high altitudes in Africa, has increased. Breeding programs aiming at resistance to diseases and pests, increased yield, special shapes and size of plant, and improvement of cup quality have produced new commercial varieties. Natural and bred botanical interspecific hybrids, such as "Hibrido de Timor", a spontaneous hybrid of *C. arabica* and *C. canephora*, are used to create progenies that are resistant to rust like Robusta but have Arabica flavor characteristics. This is accomplished starting from traditional varieties with a small genetic base (Caturra, Catuai), and introducing genetic variability from

spontaneous trees from Ethiopia or Sudan. Commercially important ones are Catimor: a hybrid created by backcross selections of a hybrid between "Hibrido de Timor" and "Caturra vermelho" (a natural mutant of *bourbon* found in Brazil), and Icatu: an interspecific hybrid between a colchicine-induced tetraploid Robusta plant and the Arabica cultivar "Mundo Novo". A similar progeny has also been developed in Colombia as "Colombia". The selection cycle can now be reduced from 30 years down to less than 10 years by multiplying in-vitro selected F1 hybrids [8]. An interesting low-caffeine somaclonal variation, obtained from *Arabica* x *racemosa* hybrids, "Aramosa", has been found highly resistant to drought and early ripening and has good cup characteristics [9]. *Coffea canephora* has a very high genetic variability and is usually propagated by cuttings in nurseries.

The best soil for planting is friable, porous, well drained, rich in organic matter, and slightly acidic. The soil must be deep for Arabica. The plants are cultivated on sheltered slopes arranged in squares or following the contour of the land protected from wind and frost also by intercropping at early stage with various suitable crops, and by rows of trees. For Arabica, the spacing between each plant can even be less than 1×1 m, with a density of 10 000 or more trees per hectare, depending on variety, climate, and the choice of either single-stem or multiple-stem cut. The best spacing for Robusta is 3×2 m.

Various pests attack coffee. Beside CLR and CBD, other harmful mycetes that deserve mentioning are *Fusarium* (*Gibberella*) *stilboides*, fusarium bark disease, and *Fusarium xylarioides*, tracheomycosis or fusarium vascular wilt, the most serious disease affecting Robusta, also affecting Arabica. Nematodes can invade the roots (e.g. *Meloidogyne coffeicola*). Among the insects that attack coffee the most damaging are *Hypothenemus hampei*, "broca", coffee berry borer (CBB) and *Perileucoptera coffeella*, "bicho mineiro". Now that rust-resistant varieties have been introduced, CBB has become the most important pest, present almost in all producing countries, causing a premature fall of berries and damaging the seeds within the berries.

Table 1. Commercial coffees

	***Coffea arabica* L. – Arabica coffee**	***Coffea canephora* Pierre – Robusta coffee**
First described by, date	LINNAEUS, 1753	PIERRE, 1895
Botanical varieties	*typica*, *bourbon*	*robusta*
Indigenous to	Eastern highland	Eastern central rainforest
Optimal growth	temperate equable climate	warm humid climate
Altitude	700–2000 m	0–800 m
Average yearly temperature	15–23 °C	18–27 °C
Maximum temperature	25 °C	30 °C
Annual rainfall	1500–2200 mm/m^2	2200–3000 mm/m^2
Plant	self-fertile shrub or small tree bearing after 3–4 years	self-sterile shrub or small tree bearing after 2–3 years
Chromosomes (2n)	44	22
Root system	deep	shallow
Leaf	small, glossy, oval, (12–15) × 6 cm	large, broad, corrugated, (15–30) × (5–15) cm
Flower	after rain, small white to cream	irregularly, large, white, sometimes pink
Fruit, a drupe (cherry or berry; it contains two seeds surrounded by parchment with the flat grooved faces against each other)	oblong ellipsoid, 15 mm long, several on each leaf axil in loose clusters, crimson or yellow, 8–9 months to ripen	ellipsoid, striated when dry, 12 mm long, in tight axillary clusters, crimson then black, 9–10 months to ripen, dries on branch
Seed (bean)	oval, flat, deeply grooved, 5–13 mm long	oval to round, grooved, 4–8 mm long
Trade name	Arabica	Robusta
Relative importance (2006)	66 %	34 %
Cup flavor of roasted and brewed beans	mild, aromatic, acid	woody, earthy
Caffeine content of bean (dry basis)	0.6–1.4 %, average 1.2 %	1.7–4.0 %, average 2.2 %

3.2. Harvesting and Processing [10, 11]

A transverse section of a coffee cherry is shown in Figure 1.

3.2.1. Arabica

Arabica coffee is harvested by selectively hand picking the red ripe cherries every 1–2 weeks. In some countries near the tropics, where seasons are recognizable, ripening occurs in a rather uniform way. In such cases, when not enough la-

bor is available at harvest time, immature and ripe cherries are stripped off the branches and collected from the ground along with the overripe and dry ones. The leaves and twigs are winnowed away in the field. Often a water siphon, in which the heavier cherries sink, while leaves, twigs, and dry cherries float and are diverted, is used to carry out an initial grading of the cherries. The middle fraction containing the ripe cherries is further treated by either the dry process, in which the whole cherry is dried, or the wet process, in which the pulp surrounding the bean is fermented and washed away before the beans are dried in their parchment [12]. Raw beans recently processed in either of these ways are recognized by their color: dry-processed (or natural) beans are yellow-green to pale brown, whereas wet-processed (or washed) beans are green to blue-green.

Figure 1. Transverse section of a coffee cherry containing two seeds (courtesy Dr. E. Dentan)
Pericarp: "Skin" or exocarp, red (or yellow); "Pulp" or mesocarp, yellow-white; "Parchment" or endocarp, pale yellow
"Silverskin" or spermoderm, silvery
"Bean" or endosperm, yellow-green when dry
The site occupied by the "mucilage," yellow-white, appears black in the figure, having been dissolved away during the preparation of the sample.
A coffee cherry may contain one, two, or rarely, three seeds.

The *dry process* is applied where water is scarce (as in Ethiopia and Brazil) and to the off-grade cherries discarded during wet processing. Freshly harvested cherries are spread out to dry in the sun. They are placed in layers up to 6 cm thick, turned regularly, and sheltered from rain showers and dew. The coffee dries in 2–3 weeks, and the husks can then be removed mechanically from the beans.

The *wet process*, which uses water flowing down a slight gradient, was introduced by the Dutch in the West Indies during the first half of the 18th century and is used where enough water is available and the climate is humid. Harvested cherries are handled in bulk if they can be processed in less than one day; otherwise, they are stored under water to avoid overheating. Where the water supply is abundant, cherries are pregraded in a washing channel or a siphon tank. Where water is scarce, the cherries are supplied dry to the pulper. This reduces water consumption by half (60 vs. 120 L/kg). Pulping is done by squeezing the cherries through slots in drum or disk machines to separate the outer skin and some of the fleshy pulp (the pericarp) from the parchment coffee (the bean surrounded by the endocarp). Parchment coffee is then sorted by gravity, and floaters, light parchment, peaberries (oval beans from cherries containing only one seed), and heavy parchment are sent to separate tanks. The sticky pulp still adhering to the parchment is loosened by fermentation in a tank, either dry in the open for 24–48 h or under water for up to 72 h, depending on the altitude. The fine acid taste of some of the coffees grown at high altitudes is attributed to the long fermentation time. Adding pectic enzymes or alkali may accelerate fermentation. Fermentation is stopped by soaking parchment coffee in water.

Pulping and fermentation are sometimes combined in the "aquapulper," a pulper and demucilager, where the pulp is rubbed off the parchment mechanically. All pulp residues are washed away in a channel where the remaining skins and whole cherries, which are lighter, are flushed away and collected on wire trays. The cherries are dried in the sun for 5–10 d on wire strapping, which ensures thorough air circulation, or on barbecues. Where the climate is not sufficiently dry, sun drying can be partially or completely replaced by artificial drying in tray or tower air dryers for 24–36 h. Particular care must be taken to avoid overheating the coffee, which results in the subsequent development of a sour taste.

3.2.2. Robusta

Robusta cherries remain on the tree at maturity, undergoing a slight fermentation, which is interrupted when the fruit dries. The ripe cherries are selectively picked from the large shrubs by starting at the lower branches. The practice of stripping cherries off the tree at various degrees of maturity from green to dry, and drying, husking, and bagging them without sorting is becoming common.

Figure 2. Coffee beans of various types
a) roasted Arabica; b) roasted Robusta; c) raw Arabica; d) raw Robusta

3.2.3. Liberica and Excelsa

Liberica cherries are rather pulpy and difficult to dry. Excelsa cherries ripen a few at a time and then drop to the soil when dry. In both cases, uncontrolled fermentation occurs, which contributes to the unclean taste of their brew. Their importance is waning and they will not be discussed further.

Coffee beans of various types are shown in Figure 2.

3.2.4. Processing at the Mill

Dry cherry or parchment coffee is normally cured in centralized mills. Impurities are removed from coffee by sizing on oscillating screens and by density differences in a pneumatic "catador" or on densimetric vibrating tables. Processing rate is up to 1 t/h for cherry and 2 t/h for parchment coffee. Dehulling of the dry parchment or of the shell, which becomes brittle when it is dried, is done by impact in a centrifugal mill, usually a ribbed steel drum or a crossbar revolving in a perforated case, which also polishes the silverskin off the surface of the beans and winnows away the shells. Capacities are 0.1 t/h for hand-operated mills and up to 3 t/h for motor-operated mills. The raw coffee beans are graded by size, through revolving or flat screens with round holes, at the rate of 0.1–1.5 t/h. Peaberries, which are oval, can be separated from flat, regular beans through slot holes or by rolling them down a conveyor belt that runs upward at a slight angle. They are sold separately under the name caracoli. Grading by density is done by winnowing the beans on densimetric tables (capacity 1–4 t/h) or in catadors (capacity 0.8–1.5 t/h), where sand and stones are again removed and the product is separated into healthy beans of full weight, medium beans, lighter inferior beans (empty, insect damaged, etc.), "triage" (material rejected from superior grades), and "brisures" (bits).

Grading by color, recommended to get rid of visible defects [13], is accomplished in several ways: by hand picking (capacity < 1 kg/h per person); electronically with monochromatic equipment, used with Robustas to sort out black beans; bichromatically, by which both brown

and bleached beans are eliminated in Arabicas; or fluorimetrically at 360 nm, to eliminate "stinker" beans, which have an impure taste, in freshly cured washed Arabicas. The beans are fed into chutes on counterrotating rollers or on belts and viewed from different angles. The rejected beans are driven out by compressed air (capacity up to 150 kg/h per channel).

Figure 3. Equipment used in coffee processing (courtesy of Bühler, Uzwil, Switzerland)
A) Pneumatic aspirator, the catador, which classifies according to density; B) Vibrating separator, which classifies by size

Grading by cupping is sometimes performed in the producing countries, but more often it is done in the consuming countries. Representative samples of coffee are examined for defective beans and extraneous matter, roasted and noted for uniformity of roasting, ground and brewed in porcelain equipment, tested by smelling, and tasted by swiftly drawing a spoonful against the palate [14]. Washed Arabicas are graded according to acidity, body, and flavor. Dry-processed Brazilian coffees are subdivided in order of decreasing quality as strictly soft, soft, softish, hardish, hard, and Rioy (a typical medicinal off-taste). The best Robustas are neutral and clean, while defective ones are harsh, rubbery, or earthy.

Placing 60 or 69 kg of coffee (70 kg in Colombia) into jute bags marked with the name of the producer and the year of harvest readies the coffee for shipping. The shipping of Robusta coffee in bulk containers is now practiced.

Equipment used for separating impurities and for grading green coffee beans is shown in Figure 3.

3.3. Marketing [15]

Today one of the most important food commodities, the world green coffee market has been characterized in the past by long periods of oversupply alternating with brief periods of shortage, linked to the size of the crop. A series of short-term agreements, concluded by producing countries in an effort to avoid wild fluctuations in prices, finally led to the first *International Coffee Agreement* (ICA), signed in 1962 by both producing and consuming countries at the United Nations. The agreement, which is administered by the *International Coffee Organization* (ICO) with a head office in London, has been reviewed several times. The present (in 2006) agreement entered into force in 2001 with the signature of 44 exporting (> 99 % of all coffee produced) and 30 importing members of the ICO. All major consumer countries are represented, including the United States as a new entry. The objectives of the new ICA, which have switched in the 1990s from regulation of supply and demand through export quotas to assistance to international trade, are:

- Encouraging members to develop a sustainable coffee economy
- Promoting coffee consumption
- Promoting quality of coffee
- Providing a forum for the private sector for representatives of the private sector (traders, roasters, etc.)
- Promoting training and information programs designed to assist the transfer of technology relevant to member countries
- Analyzing and advising on the preparation of projects to the benefit of the world coffee economy

Table 2 [16] lists the total coffee production for the crop years 1993 to 1998 in thousands of 60-kg bags – the traditional trade unit – of all ICO exporting member countries.

Marketing systems have involved different types of semigovernmental agencies in the producing countries. Liberalization of trade, particularly noticeable in the 1990s, has led to price transparency and eliminated the monopoly of Marketing Boards in the sale of coffee.

In the consuming countries, coffee is traded in the following ways:

1) The "forwards market" applies to coffee before it leaves the producing country. This is usually only available to large traders and roasters who need to ensure large quantities (thousands of bags) of well-defined grades and origins throughout the year.
2) The "spot market" covers coffee once it has actually landed in an importing country. Practically all origins are available at one of the main importing ports. This is often the only way of purchasing available to small roasters who buy a few bags at a time and wish to avoid price risks.
3) The exchange or terminal market covers coffee scheduled for delivery at a set date and price in the future. Futures contracts are taken either to avoid (hedging) or to exploit (speculating) price fluctuations. The main markets are the New York Coffee, Sugar, and Cocoa Exchange (NYCSCE), where lots of 37 500 lb (ca. 250 bags) of "milds" are traded under the "C" contract, with prices in US cents per pound ex-dock, and the London International Financial Futures and Optional Exchange (LIFFE), which deals in Robustas, with 5-t lots and prices in US$ per ton, CIF (Cost Insurance Freight) selected European ports.

Three consumer issues have acquired some importance after the 1990s in the coffee trade.

Fair Trade coffee is a commodity produced in many less developed countries, sometimes in conditions and of a quality below current food standards, further exacerbated after liberalization of trade in the late 1980s and early 1990s, when world coffee prices reached a very low level, rendering the living conditions of small coffee farmers precarious. As a reaction, a new way of trading, namely "Fair Trade", was introduced in 1988 in the Netherlands to improve the working and living conditions of small farmers by direct trade, a guaranteed minimum price, prefinancing, and long-term contracts, and to reduce their dependence on the local wholesaler. Direct trade has been extended in the 1990s to other commodities and many importing countries. Although reaching only a small fraction of the coffee traded, small-scale direct procurement systems, now benefiting from the financial backing of governmental and private funds, have helped in drawing the attention of consumers in the developed countries to the question of redistribution of profits in the production areas. Major industrial users now revise their trading practices, introducing some form of direct procurement, which allows them to assist farmers to produce coffee according to their quality standards.

Organically grown coffee has picked up a few percent of trade since it appeared in the 1980s among the specialty coffees in the United States with an image of wholesomeness [17]. In the 1990s its image has moved to one of environmental protection, according to the aims of organic agriculture of working with renewable resources, maintaining genetic diversity, minimizing all sources of agricultural pollution, and considering the ecological and social impact of agricultural systems. Regulations for organic products, including coffee, which must be certified by recognized inspection agencies, have been issued [18].

Sustainability is a general approach in coffee economy that, according to a preliminary draft wording, implies conditions of production, processing, and trade for all parties involved in the supply chain that:

1) Provide an economic return that covers production and living costs plus a further margin for development,
2) Treat the environment responsibly so that natural resources remain available to future generations,
3) Secure social and working conditions in accordance with international standards, conducive to the maintenance of stable communities.

Table 3. Decaffeination by low-moisture processes

Operation	Medium	Conditions	
		t, °C	Time, h
Soaking	steam and water	22–100	0.25–5
Decaffeination	water-saturated solvent		
	dichloromethane [22]	60–100	2–12
	ethyl acetate [23]	80–105	3–12
	fats and oils* [24, 25]	95–105	6–9
Deodorization	steam	100–110	1–4
Drying	heat	40–80	0.5–10

* No longer used.

4. Decaffeination [19]

The stimulating effect of coffee is due to the presence of the alkaloid caffeine (structure, see 2); decaffeinated coffee gives a brew devoid of this effect. The presence of water (caffeic acid as a dope has been proposed [20]) is essential in decaffeination to soften and open the cellular structure of the beans and to ensure the diffusion of caffeine across the cell walls by solubilizing the caffeine – potassium chlorogenate complex. The ease of decaffeination increases with the moisture level in the beans, while the selectivity for caffeine extraction with respect to other water-soluble constituents decreases. Industrial processes, which are usually carried out with green beans, can be broadly divided into two main types: those performed at moisture levels below 50 % (usually between 30 and 45 %), and those performed above 50 % (usually between 55 and 65 %).

4.1. Low-Moisture Processes

Low-moisture decaffeination processes are applied to green coffee to avoid removing or altering fragile aromatic constituents formed during roasting. The beans are soaked in a mixer, column, or rotating drum and extracted with a nonpolar solvent in one or more columns or rotating drums. The residual caffeine level in the beans is lowered to less than 0.1 % in the dried decaffeinated beans by most national regulations, or to less than 3 % of the amount initially present (the commercial practice in some countries). The beans are then deodorized (solvent traces are removed by steam stripping) and dried to their initial moisture content in a tower or a fluidized-bed drier under atmospheric or reduced pressure. The solvent is recovered by batch or continuous evaporation, or by steam stripping of the caffeine under vacuum. Losses due to leaching of hydrosoluble material are low, and caffeine, containing a few percent of waxes from the surface of the beans, is recovered and purified by successive crystallizations to pharmaceutical grade for use in soft drinks and medicines [21]. Typical operating conditions are given in Table 3.

4.2. High-Moisture Processes

In high-moisture processes, green or roasted coffee beans are soaked in water until they have reached the required moisture level. Decaffeination is carried out by dissolution with an aqueous solution of 10–30 % noncaffeinic, soluble coffee solids. The resulting caffeine-enriched solution is then decaffeinated either by liquid – liquid extraction with any of the solvents used in the low-moisture processes or by adsorption of the caffeine on activated carbon or on ion-exchange resin. This solution is then used to decaffeinate new beans.

Alternatively, the swollen green beans may be decaffeinated with fresh water. After removal of the caffeine the solution is concentrated and reabsorbed on the predried decaffeinated beans from which it has been obtained, thus replacing noncaffeine solids otherwise lost. Losses of coffee solids are usually higher with adsorption processes than with solvent processes. Losses on the adsorbent may be reduced by precharging it with sucrose or by regenerating it with acetic acid or ethanol solutions. In addition, pretreatment of active carbon with formic or hydrochloric acid reduces discoloration of the beans. Table 4 gives typical operating conditions.

Table 4. Decaffeination by high-moisture processes

Operation	Medium	Conditions	
		t, °C	Time, h
Soaking	water [26]	70–100	0.2–2

Propane *	97–120	10–15	6	[35]

* Not used.

4.3. Processes Using Supercritical Media

Supercritical carbon dioxide, i.e., at temperatures and pressures above the critical point of 31.06 °C and 7.38 MPa (73.8 bar), can be used to decaffeinate coffee by a process called destraction by its inventor K. Zosel. The supercritical medium in a pressure vessel is circulated through moist coffee, where it becomes charged with caffeine. It is then passed through a second pressurized vessel containing an adsorbing medium such as activated carbon, resin, or water, which retains the caffeine. The solubility of caffeine increases with the density of supercritical carbon dioxide, thus increasing with pressure at constant temperature and decreasing with temperature increases at constant pressure. This property can be used in the separation step. Besides carbon dioxide, which is employed in at least one industrial decaffeination plant, other gases have also been proposed for decaffeination (Table 5).

Both carbon dioxide and propane can also dissolve caffeine in the liquid state below the critical temperature. The pressure – temperature diagram of carbon dioxide is given in Figure 4, and a scheme of decaffeination using supercritical carbon dioxide is shown in Figure 5.

Figure 4. Pressure – temperature diagram of carbon dioxide
Densities from 100 to 1200 g/L are given as the third dimension [36].

4.4. Coffee Treatments Other than Decaffeination

Coffees processed by methods other than decaffeination are marketed in Germany. Green coffee beans are either treated for several hours with supersaturated steam (the Lendrich process) or washed with dichloromethane. Roast coffee beans can be washed with liquid carbon dioxide (the Bach process). All of these processes are claimed to make coffee more easily digested by removing irritating substances formed at roasting or their precursors in the green bean. Clinical and epidemiological research does not show a direct relationship between the removal of specific constituents other than caffeine (and cafestol/kahweol) and the physiological effects of drinking coffee.

5. Roasting [37, 38]

The stone-hard blue- to yellow-green raw coffee bean of density 550–700 g/L has a sweet astringent taste and a weak "green" aroma. During the roasting process, which occurs at ca. 200 °C, the coffee bean develops a brittle structure, a dark brown color, and a characteristic flavor and aroma [39]. At the beginning of roasting, for temperature increases up to 120–150 °C, moisture is released while the beans contract slightly and become paler. Browning reactions start, and the beans begin to swell and release some gas, mostly carbon dioxide, with moisture and some carbon monoxide. The reaction becomes exothermic, and above 180 °C, the main aromatic constituents form. Pressure buildup in the beans is said to reach 1.5–2.5 MPa, and, when the bean has almost doubled its volume [40], the cellular structure ruptures [41]. The final temperature reached by the bean is 190–240 °C, with roasting losses ranging from 13 to 15 % for a light-roasted coffee, consumed in northern Europe, and up to 20–22 % for a dark roast, typical of southern Europe.

Parameter*													
Roasting losses, %	0	0.7	1.3	2.3	3.1	3.8	5.5	6.8	7.8	9.2	10.8	12.1	16.2

*Average of figures obtained with four different washed Arabica samples. **Total organic carbon is quantitatively linked to the volatile aroma formed during roasting.

Figure 6. Changes occurring in coffee beans during roasting
(courtesy Dr. G. Pictet)

Figure 6 shows the temperature profile, roasting losses, moisture content, apparent bulk density, and volatile aroma released by Arabica beans with an initial moisture content of 10 %, heated up to 240 °C in 12 min. Similar graphs are obtained with roasting cycles of 6–18 min by adjusting the ratio of beans to hot air. With faster roasting cycles, down to less than 2 min, uniformity of roasting throughout the bean is reduced. For a given roasting loss, the apparent bulk density, quantity of aroma released, and extractable solids at brewing increase. Robustas need longer roasting times to attain the same roasting losses as Arabicas. On subsequent cooling, which may be accelerated by quenching the roasted beans with water, residual carbon dioxide is still present in the beans and is slowly released over a period of days.

5.1. Roasters [42]

Green coffee is delivered either in palletized bags or in bulk. After the coffee is cleaned, it is stored in silos and then automatically conveyed for volumetric or gravimetric dosage and roasting. Roasters can be subdivided into conduction roasters, with direct flame heating, and convection roasters, employing preheated gas either in a laminar or a turbulent flow (fluidization). There are many roaster models, operating both batchwise or continuously, with capacities ranging from a few kilograms to more than 5 t/h. These range from manual to fully automatic, some having the capability of programming the roasting cycle. They are operated with either gas or fuel oil, consuming energy at the rate of 1–2 GJ per ton of green coffee. Models with gas recirculation and catalyzers can reduce gas emission below 50 mg/m^3. Odors and emissions are suppressed by a water spray lasting 10–15 s and by passing steam through the catalyzer [43]. Regular automatic cleaning cycles in some models avoid the buildup of tars. In the newer convection models, roasted coffee with a density of 300–450 g/L can be prepared by modulation of the temperature and the ratio between the hot gas and beans. That is, a roasting temperature ca. 300 °C, short exposure time (2–3 min), and high air : bean ratios produce low-density roasted coffees; this so-called high-extraction or fast-roasted coffee can yield up to 20 % more extractable matter when brewed and a more pronounced taste. Less spectacular results can also be attained by using traditional conduction – convection roasters at high final temperature conditions and low gas volumes [44 – 46]. Figures 7, 8, and 9 show examples of batch and continuous industrial roasters (courtesy of Probat, Emmerich, Germany).

5.2. Grinding [47]

Grinding of the brittle beans is easily done in mills that vary in capacity from a few grams for household equipment to 4 t/h for industrial roll mills. The average particle size of the ground coffee depends on the extraction equipment to be used. Characteristic particle sizes in millimeters for various brewing methods follow:

Industrial extracts	1.0 to bean halves
U.S. drip, percolator	0.7–1.0
Filter	0.4–0.6
Espresso	0.3–0.4
Middle East	< 0.1

5.3. Packaging [48]

Unlike raw beans, roasted coffee spoils relatively quickly if unprotected from oxygen and moisture. At ambient temperature, some detrimental changes in brew flavor occur.

	Beans	Ground
Fresh roast	6 d	48 h
Weaker aroma	10–12 d	4–6 d
Stale	4–6 weeks	2 weeks

The presence of residual carbon dioxide of ca. 4 cm^3/g, which corresponds to an overpressure of 0.5 MPa [49] in the beans, precludes packing of freshly roasted coffee in airtight packages. Coffee is either prepared for market as beans in non-airtight packs or allowed to degas for up to 48 h and then filled under vacuum in metal cans or in plastic containers impermeable to air and to carbon dioxide. Coffee is more often prepared for market preground and packed in brick packs or cans after degassing or under an initial slight vacuum in flexible bags with a one-way degassing valve. In this case, 2–4 h of degassing is sufficient [50]. In pressure-tight cans, optimal aroma is reached after a few weeks if packeged in a protective atmosphere of inert gas.

6. Brewed and Instant (Soluble) Coffee

Roasted coffee is either sold as whole beans or already ground for brewing and immediate consumption, or further processed at the coffee plant where, after extraction, the soluble solids are concentrated and dried to produce instant coffee.

6.1. Brewing [51]

In spite of the apparent simplicity of coffee brewing–just a pinch of grounds dispersed in hot water–a bewildering array of domestic and professional brewing tools have made their appearance, giving origin to different consumption styles and cultures. The traditional brewing technique, still applied in several parts of the world, consists of boiling coarsely ground coffee (in the Nordic countries) or very finely ground coffee (in the Middle East) in water, infusing it for several minutes (up to 30), and serving it without separation of the grounds.

The main problem being the separation of the unpleasant spent grounds from the beverage, various ingenious filtering devices–sometimes lined with filter paper or cloth–evolved, fitting to plain or reversible pots. For example, in a typical household percolator, hot water is continuously recirculated through a bed of coarsely ground coffee (average particle diameter 0.7–1.0 mm). The extract is then filtered when it has reached the desired concentration of soluble solids. In more recent automatic drip coffee machines, soluble solids can be leached from a bed of ground coffee (average diameter 0.4–0.6 mm) kept on a

filter at slightly above atmospheric pressure for up to 15 min with or without recirculation.

The request for faster preparation of a cup arose around the beginning of the 20th century, when the first so-called "espresso" machine was built by Bezzera. Speed of percolation was increased at that time by steam-generated water pressure. By use of overpressure, as in household and food service espresso machines, the water passes through a bed of coffee (average diameter 0.3–0.4 mm) at a temperature depending on the desired pressure. A nimbler control of brewing conditions was made possible using compressed air boosters (as in a patent by Illy [52]), or lever-operated pistons or electrically-driven pumps. In all of these instances, production of water pressure is disconnected from the temperature, which remains slightly below its boiling point. The yield of soluble solids can attain 20–30 %, depending on the grind and the technique employed [53].

6.2. Instant Coffee Manufacture [54, 56]

6.2.1. Extraction

In an instant coffee plant, coarsely ground coffee (average diameter 1.0 mm to bean halves) is extracted with softened water in a battery of five to eight percolation columns, with cell capacity from a few kilograms up to 1 t. The process operates semicontinuously, with water at 160–180 °C passing as a countercurrent to the coffee from the most extracted cell to the one just filled with freshly ground, roasted coffee. The cells are divided into two groups: the *hot* cells at a temperature of 140–180 °C under a pressure of 1.4–1.6 MPa (14–16 bar), and the *cold* cells at a temperature of ca. 100 °C. In the hot cells, the extraction of difficult material, carbohydrates in particular, takes place; in the cold cells, the most flavorful material is extracted. Extract is withdrawn from the fresh cell, cooled to 4–5 °C in a heat exchanger, and then sent into a scale in amounts that depend on the desired yield (35–55 %) from the roast and ground coffee and on the concentration of the extract. At the end of the *withdrawal* period, a fresh cell enters the circuit, while the spent grounds are evacuated from the bottom of the most extracted cell. Figure 10 shows an extraction battery with six cells [56].

Figure 10. Extraction battery of six percolators with temperature profile [56]

The major manufacturers now use shorter percolators with more finely ground roast coffee. The shorter extraction times thus obtained, together with new techniques to protect and rectify the volatile aroma, improve quality, which now approaches that of a brew, even at extraction yields around 50 % [57].

6.2.2. Concentration

Extract at a concentration of 30 % or more can be dried directly, but with a high loss of aromatic constituents. The extract coming out of the hot section contains fewer volatile aromatic constituents than cold extract. The hot extract can be evaporated to a concentration of 50–60 % after flashing or steam stripping the volatile aroma or by separating hot from cold extracts; it then can be mixed with diluted aroma or *cold* extract to reach a *standardized* extract at ca. 40 % concentration. A more gentle concentration process

involves freezing the extract and then mechanically separating the almost pure ice crystals. By this technique, coffee extract can be efficiently concentrated up to 35–40 % with relatively low flavor or product losses.

6.2.3. Spray-Drying

Cooled and clarified extract is nebulized through a rotary or static pressure nozzle into the top of a spray tower, dried by a cocurrent flow of hot air at ca. 250 °C, and collected in the conical bottom of the tower at a temperature ca. 50 °C. Coarse, free-flowing nondusty powders with a mean size of 200–300 µm and a residual moisture of 2–4 % are obtained. Bulk density can be adjusted between 230 and 280 g/L by foaming the extract with an inert gas, usually carbon dioxide or nitrogen. The powder can be agglomerated to a coarse structure by rewetting, which makes it easy to spoon and mix with hot water. A spray-drying tower is shown in Figure 11.

Figure 11. Spray-drying tower
(courtesy of Niro Atomizer, Copenhagen) [58]
a) Cooled and clarified coffee extract (30–50 % solids); b) Nozzle assembly; c) Hot air (ca. 250 °C); d) Transition cone for uniform spray – air mixing flow in the upper region of the dryer; e) Exhaust air to dry collector for fines recovery by cyclone or bag filter (reslurried in the feed or agglomerated); f) Chamber cone; g) Powder discharge (over 90 % recovery)

6.2.4. Freeze-Drying

During this operation, extract is frozen with separation of ice crystals, which are then sublimated under vacuum. The process entails several steps:

Primary Freezing. Cold extract at 4–5 °C is prechilled to soft ice slush at − 6 to − 8 °C. The bulk density and, to some extent, the color of the final product depend on the degree and nature of foaming, with nitrogen giving a lighter product than carbon dioxide.

Secondary Freezing. The soft ice is cooled down stepwise to − 40 to − 50 °C on a steel belt, on trays, or on drums. The size and the rate of formation of ice crystals influence the color and aroma retention of the product. Larger crystals give a darker product, with freezing times of 10–180 min, while light-colored products can be obtained by fast freezing for 30–120 s on freezing drums.

Grinding. The ice slabs at a temperature of − 40 to − 45 °C are ground and sieved to the desired size. Undersized or fine particles are reworked. The frozen particulate is put into trays, which are loaded on carriers and introduced into the drying section.

Drying. The drying chamber may be a batch type, where the trays remain fixed on heating plates through the drying operation, or a semicontinuous type, in which the tray carriers move through a vacuum lock into a drying tunnel, where they pass through successive temperature zones and exit through another vacuum lock. In a fully continuous freeze dryer, the frozen coffee particulate is fed directly into the vacuum chamber from a feed tank, progressing through the dryer to a discharge tank. The drying chamber is fitted with heating plates, which provide the sublimation energy to convert ice into water vapor. The vapor is collected on cooled condensers, and a pumping device keeps the chamber pressure lower than the triple point of water (613 Pa). A product with 1–4 % moisture at a temperature of 45–50 °C is obtained.

Table 6. Composition of dried raw coffee beans *

Constituent	Proportion, wt %*		Components
	Arabica	Robusta	
Carbohydrates	48.3–54.0	48.6–55.0	
Monosaccharides	0.2–0.4	0.5–0.7	fructose, glucose, galactose, arabinose
Oligosaccharides	5.1–8.6	2.2–6.6	sucrose
Polysaccharides	43.0–45.0	46.9–48.3	soluble and insoluble polymers containing mannose, galactose, glucose, arabinose
Acids and phenols	8.2–11.0	10.1–16.3	
volatile	traces to 0.06		acetic, formic acids
nonvolatile aliphatic	2.0–2.9	1.3–2.2	citric, malic, oxalic, quinic acids
phenolic	6.2–8.1	8.8–14.1	depsides of caffeic, ferulic, *p*-coumaroyl acids, and quinic acid; in Robustas also with amino acids
Lipids	8–17		
	15 average	10 average	fatty acids as triglycerides, diterpene esters, sterol esters, free acids
Amino acids	10.3		mainly as proteins
free	0.5	0.8	
Methylxanthines	1.2	2.2	caffeine, traces of other purines
Trigonelline	1.0	0.7	
Minerals	4.2	4.4	
potassium	1.7	1.8	

* The contribution of the analytical error to inter- and intraspecies variations may be larger than natural variation.

6.2.5. Aromatization

Volatile aroma from grinding gas, or from steaming of ground, roasted coffee prior to extraction is emulsified with oil from pressed, roasted coffee or spent grounds and sprayed on the powder, at a level of 0.3–1 % during the filling operation.

7. Composition [59]

The main differences in the composition of Arabica and Robusta raw beans lie in the relative amounts of lipids and trigonelline, which are higher in Arabicas, and of chlorogenic acids and caffeine, which are higher in Robustas. Table 6 shows the composition of Arabica and Robusta coffees.

7.1. Carbohydrates [60]

Carbohydrates constitute ca. 50 % of the raw bean. Although their content appears to be marginally higher in Robustas than in Arabicas, there are no major qualitative differences between the two botanical species. Sucrose is the main oligosaccharide, and polymers of arabinose, galactose, glucose, and mannose constitute both the soluble polysaccharides in the cells and the insoluble ones, which form, with proteins and the chlorogenic acids, the structure of the cell walls [61]. Table 7 lists the makeup of the carbohydrate portions of raw Arabica and Robusta coffee beans. Some structures that have been partially identified are listed in Table 8

Table 7. Carbohydrates in dried raw beans

Fraction	Proportion, wt %	
	Arabica	Robusta
Monosaccharides *	0.2–0.4	0.5–0.7
Oligosaccharides *	5.1–8.6	2.2.–6.6
Polysaccharides, composed of:	43.0–45.0	46.9–48.3
Mannose	21.3–22.5	21.7–22.4
Galactose	10.4–11.9	12.4–14.0
Glucose	6.7–7.8	7.8–8.7
Arabinose	3.4–4.0	2.8–4.1
Total	48.3–54.0	48.6–55.0

Fructose, glucose, galactose, and arabinose (traces). ** Mainly sucrose.

Roasting favors polysaccharide depolymerization, improving mannan extractability at high temperature (180 °C), liberation of oligo- and monosaccharides, reaching a maximum at medium roasting, followed by pyrolysis at dark roasting. Table 9 lists the carbohydrate makeup of roasted coffee beans.

During high-temperature industrial extraction, polysaccharides are partially hydrolyzed to mono- and oligosaccharides [63] independently of species. Tables 10 and 11 show the extraction behavior as a function of roasting degree of the

Table 8. Carbohydrate structures that have been partially identified in dried raw coffee beans

Fraction	Proportion, wt %		Structure
	Arabica	Robusta	
[Galacto]mannan	22		Mainly mannose as straight chains of β-(1-4)-mannan, with little galactose. Storage carbohydrates of molecular mass range 800–800 000; extremely hard and poorly soluble.
Arabinogalactan	14–15	16–17	Polymers composed of β-(1-3)-arabinogalactan, probably covalently linked to proteins. In Arabica there is a higher branching frequency and a higher level of terminal mannose than in Robusta. Structural cell-wall components of molecular mass range 200–200 000
Cellulose	8		β-(1-4)-Homoglucan. Structural cell-wall components.
Hemicelluloses	traces		Contain rhamnose (0.3 %), xylose (0.2 %) from residual parchment.

Table 9. Carbohydrates in dry roasted beans

Fraction	Proportion, wt %	Components	Behavior during roasting
Monosaccharides	0–2.0	glucose, fructose, arabinose (traces), and galactose	disappear at dark roasting
Oligosaccharides	0.4–2.8	sucrose	decreases, disappearing at dark roasting
Polysaccharides [62]		mannan	is depolymerized to a molecular mass range of 200–80000 and its high-temperature extraction behavior improves sharply
		arabinogalactan	is depolymerized to a molecular mass range of 200–50000 with a decrease in the degree of substitution of galactan chains from 1:7 to 1:12 arabinose:galactose
		cellulose	rather stable

Table 10. Carbohydrates in soluble extract from coffee roasted at three different degrees, wt % by monosaccharide constituents and by their polymers (glycans) (determined as single sugars)

Components	Light roast	Medium roast	Dark roast
Arabinose	2.4	1.7	1.5
Galactose	20.0	17.8	13.9
Glucose	0.9	10.4	0.7

Total	32.6	31.2	32.7

Table 11. Carbohydrates in soluble extract from coffee roasted at three different degrees, wt % by degree of polymerization observed (determined as total monosaccharide)

Components	Light roast	Medium roast	Dark roast
Monosaccharides	3.34	2.89	2.01
Oligosaccharides	8.03	9.57	7.38
Polysaccharides	20.85	18.46	23.22

carbohydrates of an Arabica coffee at extraction yields of around 39 %.

While the amount of mannan in a coffee brewed at ca. 95 °C is rather low, it increases to up to two-thirds of the amount present in green beans when coffee is extracted at 180 °C. This material is, however, poorly soluble and precipitates on standing [64]. The molecular mass profile of the carbohydrates in a commercial soluble coffee allows inferences to be made about the way it was manufactured, and, in particular, the degree of high-temperature hydrolysis that was applied during industrial extraction to be estimated. The free and total carbohydrate content of commercial soluble coffees is given in Table 12.

The amount of specific free and total carbohydrates in a soluble coffee indicates if extraneous material, such as cheap maltodextrins or worthless husk and hulls, discarded during dry processed green coffee production, were used, either dry or roasted [66, 67] (Table 13).

Table 12. Free and total carbohydrate content of soluble coffee, wt % [65]

Component	Free		Total	
	Range	Average	Range	Average
Xylose			0.11–0.28	0.17
Arabinose	0.75–2.01	1.17	2.35–5.80	3.908
Fructose	0.05–0.42	0.12		
Mannose	0.13–2.62	0.53	10.2–19.7	14.2
Glucose	0.00–0.43	0.12	0.57–1.51	0.97
Galactose	0.27–0.72	0.47	13.5–24.7	19.5

Table 13. Carbohydrates used to determine the purity of commercial soluble coffees, wt %

	Pure soluble coffee	Maximum tolerable level
Free		
Fructose	0.05–0.42	0.60
Glucose	0–0.43	0.50
Sucrose	0.01–0.64	0.80
Maltose	0	absent
Total		
Glucose	0.57–1.51	1.80
Xylose *	0.11–0.28	0.40
Sugar alcohol	0.11–0.28	0.40
Mannitol **	0.02–0.22	0.30

* Xylose makes up around 50 % of the woody parchment surrounding the beans.
** From husks [68] somewhat unstable on roasting.

7.2. Acids [69]

A series of aliphatic acids, common in cellular metabolism, has been identified in the raw bean. The concentration of some increases during uncontrolled fermentation, and the C_2– C_6 aliphatic acids with their ethyl esters may contribute to the fruity and impure off-flavor of the "stinker" beans, which survives roasting. Table 14 lists the aliphatic acids in dried raw coffee beans.

Volatile acids are formed during roasting by thermal degradation of carbohydrates and nonvolatile acids. Table 15 shows the aliphatic acids in roasted coffee beans. Phosphoric acid (Arabica 1.55 g/kg, Robusta 2.8 g/kg) increases with roasting degree, particularly in Robusta [70].

More characteristic are the phenolic acids, which exist as depsides (i.e. intermolecular esters of aromatic hydroxycarboxylic acids, where the carboxyl group of one acid is esterified with the phenolic OH group of the other) with quinic acid and are known as chlorogenic acids (see Table 16). Quinic acid itself is also present in unusually large quantities in the free state (0.55 % in Arabica and 0.35 % in Robusta beans), with caffeic acid (0.2–0.3 % free in the raw bean) and ferulic acid (also present free in trace amounts in the raw bean).

The ratio of monochlorogenic to dichlorogenic acids is related to the quality of a cup of coffee. It is lower in Robusta than in Arabica beans, and in immature or discolored beans, in which an excess of dichlorogenic acids may be responsible for the lingering metallic taste of the roasted infusion. During roasting, many reactions occur, such as decarboxylation, dehydration of the quinic acid moiety, lactonization, isomerization, polymerization, and reactions with sugars like sucrose. The feruloylquinic acids are thermally stable and survive roasting, while free quinic acid increases. At short roasting times (< 120 s), dCQAs are hydrolyzed into CQA and CA. 5-CQA rapidly undergoes esterification with carbohydrates and proteins, producing bound chlorogenic acid. On longer roasting times, phenolic and quinic moieties start degrading, generating phenols (4-ethylcatechol, catechol, phenol hydroquinone, pyrogallol [74]. The proportion of chlorogenic acids in beans of various roasting degrees is shown in Table 17.

Between 50 and 90 % of the chlorogenic acids pass into domestically brewed coffee and up to 100 % into industrial extracts, where neochlorogenic acid becomes the most important phenolic acid present (30 % of the total). Further isomerization or hydrolysis of the lactones formed at roasting may be responsible for this increase. Three stable lignan-like acidic dimers and trimers, named caffeicins, are formed on

Table 14. Aliphatic acids in dried raw beans

Acid fraction	Proportion, wt %			
	Arabica	Robusta	Component

Robusta	8.8	3.5	2.1	0.2

roasting, and are present in roasted and instant coffees [76]. Table 18 shows the proportion of chlorogenic acids in industrial extracts.

A good correlation exists between titratable acidity of the roasted coffee infusion, to which phosphoric acid (0.2–0.3 %) also contributes, and the acid taste of the cup of coffee. The correlation with pH, which may vary between 4.7 and 5.5, is less clear; for example, pH is lower for washed coffees than for natural coffees and for extracts than for household infusions. The sour taste of infusions that have been kept warm for a period of time is due to an increase in free acids, in particular quinic acid formed by hydrolysis of esters, depsides, and lactones, as well as to loss of pyridine.

Table 18. Chlorogenic acids in industrial extracts, wt % [77]

Component	Quantity
n-Chlorogenic acid	0.7–1.9
Cryptochlorogenic acid	0.8–2.3
Neochlorogenic acid	1.0–3.5

Cafestol

Kahweol (15–50% of cafestol in Arabicas)

Atractyligenin (R = H)
and glycosides
(R = 2-O-β-D-glucopyranosyl
or 3'-O-β-D-glucopyranosyl-
2'-isovaleryl-β-glucopyranosyl)

7.3. Lipids [78]

Lipids constitute 15–18 %, average 15 %, of Arabica and 8–12 %, average 10 %, of Robusta raw beans. The actual range may be smaller.

The content of unsaponifiable matter is relatively high. The lipids can be subdivided into two chemically different fractions: the wax, which constitutes the outermost layer of the bean (0.2 – 0.3 %), and the oil, located inside the endosperm. The qualitative lipid composition differs only slightly between Arabicas and Robustas.

The main fatty acids are linoleic (40–45 %) and palmitic (25–35 %) acids. The fatty acid composition of the outside wax layer, rich in the stable saturated arachidic, behenic and lignoceric acids, differs from that of the oil, which contains mostly the $C_{16} - C_{18}$ acids. Triglycerides remain virtually unchanged during roasting. The free fatty acid content, higher in unwashed beans than in washed beans, increases during storage and roasting.

Fatty acid esters of diterpenes from the kaurane family are cafestol, present both in Arabica and in Robusta coffees, 16-*O*-methylcafestol, present only in Robusta beans, and kahweol, present mainly in Arabica beans. These three compounds are specific to coffee and constitute about 20 % of the lipid fraction[79]. The presence of 16-*O*-methylcafestol in a commercial roast and ground coffee sample indicates that the blend contains Robusta coffee [80]. Another diterpene of the kaurane family present in small amounts in coffee is atractyligenin, bound in various glycosides [81].

Table 19 shows the composition of lipids in dried raw coffee beans.

Table 19. Composition of the lipid fraction of dried raw beans

Lipid fraction	Proportion, wt %	Components
Triglycerides	70–80	mainly esters of linoleic and palmitic acids
Free fatty acids	0.7–2.7	higher in Robusta [83]
Diterpene esters	15–18.5	mainly esters of palmitic and linoleic acids
Triterpene, sterol, and methylsterol esters	1.4–3.2	
Free diterpenes	0.1–1.2	
Free triterpenes and sterols	1.3–2.2	mainly sitosterol, stigmasterol, and campesterol
Phospholipids	0.1	
Hydrocarbons	traces	mainly squalene and nonacosane
5-Hydroxytryptamides	0.3–1.0	amides of arachidic, behenic, and lignoceric acids
Tocopherols	0.3–0.7	α, β-, and γ-isomers

The free alcohols are liberated from the esters during roasting, and cafestol and kahweol are further decomposed to volatile dehydro derivatives, while 16-*O*-methylcafestol is stable even at high roasting temperatures. Free atractyligenin is formed by decomposition of its glycosides.

The composition of the sterol fraction is virtually unaffected during roasting and it was also

proposed as a means to evaluate the relative proportions of Arabica and Robusta beans in commercial roasted coffee blends.

Small quantities of the antioxidants, α-, β- and γ-tocopherols, and 5-hydroxytryptamides have been identified. The content of tryptamides in the wax increases with ripening of the cherry at the expense of tryptophan and decreases on storage and also after various treatments of the bean. For example, the reduced level in treated coffee (by steaming or by solvent washing) is claimed to be an index of the reduction of irritating substances in coffee. Tryptamides are decomposed by roasting, and their relationship, if any, to health effects of the brew is at least doubtful [84].

5-Hydroxytryptamides

n = 18: Arachidonamide 33%
n = 20: Behenamide 57%
n = 22: Lignoceramide 10%

0.5–2.5 g/kg of raw coffee; they correspond to 160–175 mg of serotonin; 25–50% is lost on roasting

The content of lipids in a cup of coffee depends on the brewing method and can reach a few percent in brews made from finely ground Turkish coffee or when ground coffee is boiled with water; it is insignificant in filtered coffee infusions (for physiological significance, see Section 8.3). Small amounts of oil (between 0.2 and 1 %), obtained from roast and ground coffee or from spent grounds, are often used as support for the reincorporation of volatile aroma into an instant coffee powder, but the amount of oil present in the cup is usually negligible.

7.4. Nitrogen Compounds

7.4.1. Amino Acids, Peptides, and Proteins [85]

The estimated sum of free and bound amino acids present in the raw bean is based on the total Kjeldahl nitrogen:

$$\text{Protein } \% = \text{totalnitrogen} - (\text{purinicnitrogen} + \text{betainicnitrogen}) \times 6.25 \ \%$$

Values range from 8.7–12.2 % of the dry weight. No major differences exist between Arabica and Robusta, although the higher concentration of sulfur-containing amino acids in Robustas may be responsible for the differences perceived in the volatile flavor between the two species. Table 20 shows amino acids and proteins in dried raw bean.

Table 20. Amino acids and proteins in dried raw beans

Nitrogenous fraction	Proportion, wt %	Components
Free amino acids	0.2–0.8	glutamic acid, aspartic acid, γ-aminobutyric acid, alanine, proline, and serine are the most important; total concentration is possibly lower in Arabicas than in Robustas
Proteins	7.9–12	composition near that of the free amino acids, with 20 % of glutamic acid and 10 % each of both aspartic acid and leucine; histidine, cysteine, and methionine are also present in small quantities
Soluble proteins	25–40 %	isoelectric point at pH 5.7 for Arabicas and pH 6.3 for Robustas
Structural proteins (15–25 % soluble in alkali)	60–75 %	linked with polysaccharides and chlorogenic acids in the cell wall

Only traces of free amino acids remain after roasting since they are thermally unstable, undergoing Maillard reactions with reducing sugars, to release volatile components and form melanoidins, a polymeric material. Up to 40 % of the proteins are denaturated and decompose during roasting, although one-half of the amino acids present in the raw bean remain as apparent polypeptides with the exception of arginine, which is completely degraded. All available polypeptides are extracted at 30 % extraction yield and constitute 10–12 % of an industrial extract.

7.4.2. Purines and Nucleic Acids

Several purines have been identified in the raw bean. Among them, only caffeine, a physiologically active ingredient of coffee, is present in appreciable amounts. Nucleic acids of unknown structure have also been isolated. These are shown in Table 21.

Table 21. Nucleic acids and purine bases of raw bean

Fraction	Proportion, wt %		Components
	Arabica	Robusta	
Nucleic acids	0.7	0.8	
Purine bases	0.9–1.4	1.7–4.0	caffeine, theobromine (0.2 mg/100 g), theophylline (0.06 mg/100 g), adenine, guanine, and hypoxanthine

Part of the caffeine is present as the free crystalline base in the cytoplasm surrounding the cell vacuole. Part of it is in the cell wall, where it may be bound as a 1 : 1 π-complex with potassium chlorogenates, although the complex may also be an artifact formed during extraction [86].

Caffeine is thermally stable, and only a small part of the quantity present in the raw bean is lost by sublimation during roasting. About 85 % passes into the domestic brew and almost 100 % into industrial extracts. The caffeine content of industrial extracts varies between 3.0 and 5.1 % (dry basis) for spray-dried powders, which usually contain mainly Robustas, and between 2.5 and 3.7 % for milder freeze-dried products, which contain more Arabicas.

7.4.3. Other Bases

Trigonelline [*535-83-1*] (Arabica 0.6–1.2 %, Robusta 0.3–0.9 %) and traces of betaine and choline are present in the raw bean. Some trigonelline decomposes on roasting to nicotinic acid (niacin or vitamin PP), pyridine, and other volatile aroma constituents. Residual trigonelline is easily extracted and constitutes 0.9–1.7 % of industrial extracts.

Traces of diamines, putrescine, spermine, and spermidine have also been identified in the raw bean. They are easily decomposed during roasting.

7.5. Minerals

The ash content of green coffee averages 4.0 %, varying between 3.0 and 5.4 % (dry basis) due to the botanical or geographical origin, method of preparation, and crop year. The mineral composition of dry coffee beans is shown in Table 22.

Table 22. Minerals in raw beans

Mineral	Proportion, wt %	
Potassium	1.68–2.00	
	Milds	1.68–1.70
	Brazils	1.77–1.88
	Robustas	1.84–2.00
Calcium	0.07–0.35	
Magnesium	0.16–0.31	
Phosphate	0.13–0.22	
Sulfate	0.13	

Sodium and chloride content are low, unless the coffee has been contaminated by seawater during transport. About 90 % of the ash is water-soluble and passes into the brew with only insignificant losses at roasting. The extraction yield of instant coffee can be estimated by the measure of the potassium content, when the blend and manufacturing losses are known [87].

Trace metal concentrations in the bean, particularly of manganese, may be correlated with cup quality [88]

7.6. Products Formed during Roasting

The principal thermally reactive constituents of the raw bean are the monosaccharides and sucrose, the chlorogenic acids, the free amino acids, and trigonelline (Table 23). The terminal arabinose and galactose units of polysaccharides are split off, and the basic, sulfur-containing, and hydroxyamino acids are also easily decomposed. The lipids are relatively stable, apart from an increase in free fatty acids due to hydrolysis of the esters and some degradation of linolenic acid and unsaponifiable matter. During roasting, volatile aromatic compounds and polymeric brown pigments are formed, while water and carbon dioxide are liberated.

Caramel, melanoidins, caffeine, and several aromatic constituents are responsible for the characteristic bitter taste of roasted coffee.

Table 23. Main reactive constituents lost during roasting

Constituent	Proportion in raw bean, wt %	Fraction reacted, wt %
Carbohydrates		
Monosaccharides	0.2–0.5	≈100
Sucrose	2–7	70–80
Polysaccharides		20–25
Mannose	4–6	20–30
Galactose	3	25–30
Glucose	1	5–10
Arabinose	1	50–60
Chlorogenic acids	4.7–8.6	40–98
Nitrogen compounds		
Free amino acids	0.2–0.8	100
Trigonelline	0.1–0.8	30–80
Lipids	1	3–5

7.6.1. Volatile Aroma [89]

Two hundred and thirty volatile compounds have been identified in the aroma of green coffee [90]. The majority of these compounds survives roasting and may contribute to the roasted coffee flavor [91]. Albeit made up of almost one thousand volatile compounds so far identified (most of them common to all roasted foods [92]), aroma constitutes just 0.1% of the weight of roasted ground coffee [93].

Table 24. Important off-flavors of (green) coffee

Flavor characteristics	Odor threshold in water	Responsible chemical
Medicinal, rioy	1.0 ng/L	2,4,6-trichloroanisole (TCA) [93] *
Earthy, robusta	2.5 ng/L	2-methylisoborneol (MIB) [94] *
Musty	5.0 ng/L	geosmin *
Fruity, rotten, stinker	5–10 mg/L	ethyl esters of 2- and 3-methylbutanoic and cyclohexanoic acids [95]

* Musty/earthy off-flavors in green coffee are usually due to different combinations of these substances and of methoxypyrazines; all these substances are probably of microbiological origin and apparently occur more readily in dry-processed beans.

Furylmethanethiol
[98-02-2]

In the 1990s the focus of coffee aroma research has switched from the mere identification of more and more volatile substances to the selection of those that constitute the flavor of coffee. Two types of aroma impact substances are recognized: those that contribute to specific defects (Table 24), usually already present among the green coffee volatile compounds, and those that together constitute the aroma of roasted coffee.

A process [96] for improving the quality of Robusta coffee proposes the removal of MIB by steam heating. Since roasting destroys MIB, the Robusta flavor character of a brew may be due to a combination of several factors [97].

The coffee aroma obtained by extracting either the roasted beans or the brew with selective solvents, or by concentrating the headspace over the coffee or the brew, is separated in a gas chromatograph (GC). The smell of each peak is evaluated by sniffing the exit port of the GC, and described by notes such as burnt, cocoalike, buttery, floral, etc. (Figure 12). Once the key aroma components have been identified by mass spectrometry, their relative impact can be measured by the aroma dilution technique, which consists of injecting an increasingly diluted aroma into the GC until only a few peaks are still perceptible to the nose [98]. The most potent odorants identified in Arabica and Robusta brews are listed in Table 25 [99].

Various sensors, the so-called electronic noses, have become available for the detection of odors: chemical families such as α-dicarbonyls, pyrazines, and sulfur compounds can be recognized in the headspace when present at relatively high concentrations (at least 20 μg/L).

The cup profile can be presented as a star diagram (Figure 13) [100], in which each flavor is semi-quantitatively described by a panel of expert tasters. Star diagrams are very useful for comparing samples.

An important key aroma component is 3-mercapto-3-methylbutyl formate, which as a pure substance has a catty/blackcurrant smell, but when added at very high dilution to a (soluble) coffee infusion it strongly enhances the roasted coffee note [101].

7.6.2. Brown Polymers [102]

The nature of this heterogeneous class of yellow-brown to almost black pigments is still subject to speculation. They are formed by two main routes. In the first, small molecules in the cells, e.g., monosaccharides and sucrose, polymerize to yellow- to dark-brown caramel, which reacts with chlorogenic acids to form red- to

Table 25. Concentrations of the most potent odorants in Arabica and Robusta brews

Odorant	Arabica, μg/L	Robusta, μg/L	Odor threshold in water, μg/L
2-Furfurylthiol	19.1	39.0	0.01
(*E*)-*β*-Damascenone	1.3	1.5	0.00075
3-Mercapto-3-methylbutyl formate	5.5	4.3	0.0035
3-Methylbutanal	550	925	0.35
Methylpropanal	800	1380	0.7
Methanethiol	210	600	0.2
5-Ethyl-4-hydroxy-2-methyl-3(2*H*)-furanone	840	670	1.15
2-Methylbutanal	650	1300	1.3

black-brown humic acids [103]. These sugars also react with amino acids via the Maillard reaction [104] to form yellow- to black-brown melanoidins [105].

In the second, similar reactions may also occur in the cell wall following thermal degradation of the constituents. Partially soluble material, composed of intact mannose units linked together by galactose, arabinose, free phenolic acids, free amino acids, and peptide side chains, can be identified. These form the matrix on which the brown pigments are fixed. These processes are depicted in the following diagram:

8. Consumption and Physiology

[106 – 108]

8.1. Consumption

The leading coffee-consuming countries with annual per capita consumption and green coffee disappearance are listed in Table 26 [109]. The Nordic countries have the largest per capita consumption, while the European Union is by far the main importer, followed by the United States, where the decline in consumption has now been stopped by the improved quality introduced with specialty coffees, particularly Italian-style espresso.

Table 27. Coffee consumption in some producing countries

Country	National consumption, thousands of 60-kg bags	Average individual intake, kg per capita per annum
Brazil	15 540	5.10
Colombia	1400	1.76
Indonesia	2000	0.55
India	1134	0.06
Ethiopia	1833	1.40
Mexico	1500	0.84
Guatemala	300	1.39
Thailand	500	0.44

Among the producing countries, consumption is high in Brazil and most of Latin America, intermediate in Asia, and very low in Africa with the exception of Ethiopia (Table 27), where domestic consumption nearly approaches the exported share of national production.

Figure 12. Odor profile of a dry ground roasted coffee. The vertical axis gives the mass spectrometric abundance. Known odor thresholds are indicated on the peaks (courtesy Dr. H. Brévard)

8.2. Dietary Value

Coffee is consumed at breakfast and between meals as a stimulant, or after a meal as an aid to digestion, particularly in Latin cultures. The nutrient profile shows that a cup of coffee contributes, via nicotinic acid, a fraction of the daily nutritional requirement for niacin (vitamin B_3 or PP), in amounts increasing with the degree of roast, and might play a role in the diet of undernourished people. The composition of a cup of coffee is given in Table 28.

Figure 13. Sensory profile of a coffee brew. This sample has been characterized by a trained panel as possessing an intense overall aroma and flavor, a roasted/burnt/smoked note, and an off-flavor described as stale/oxidized (courtesy Dr. S. Bobillot)

Table 26. Green coffee disappearance in the principal importing countries [thousands of 60-kg bags (source: International Coffee Organization)] and consumption (kilograms per capita per year)

Country	2000	2001	2002	2003	2004	2005	Average	kg per capita

Table 28. Composition of a cup of coffee, mg

Component	Brew [a]	Instant [b]
Monosaccharides	0–150	15–150
Sucrose	0–200	0–200
Aliphatic acids	130–350	60–175
Chlorogenic acids	100–250	150–200
Lipids	traces	0–10
Volatile aroma	traces	traces
Caffeine	50–150	50–100
Trigonelline	30–60	15–35
Minerals	100	200
Potassium	50	100
Niacin	traces	traces
Polymeric substances [c] (by difference)	390–1230	920–1500

[a] 7.5 g of ground roasted coffee at 22 % extraction yield.
[b] 2.0 g of soluble coffee.
[c] Polymeric substances contribute to the bitter taste in the cup [110] and to the retention of aroma constituents in the soluble powder [111]; although measured as proteins and carbohydrates, they are unavailable as such after roasting.

8.3. Physiological Value

Coffee has been the subject of extensive scientific research addressing its potential impact on human health [112], caffeine attracting over 90 % of it.

Caffeine. Caffeine is the principal active ingredient in coffee, and its stimulating action is the basis for the popularity of coffee and the other caffeine-containing beverages [113, 114].

Indicative caffeine contents of coffee products are given in Table 29.

Table 29. Caffeine content of different coffee products

Product	Portion, mL	Caffeine, mg
Filter coffee	100–200	35–175
Filter decaffeinated	100–200	3–6
Espresso coffee	20–60	30–75
Instant coffee	100–200	35–115
Instant decaffeinated	100–200	2–3
Ready-to-drink	225–285	60–200

Within minutes from ingestion, caffeine is readily adsorbed and distributed through all of the tissues and organs, then it is degraded to several methylxanthines and excreted via the kidneys within a few hours [120], with only a minor proportion appearing in the urine as unchanged caffeine. Metabolization time is longer in children and in pregnant women. The physiological effects of caffeine at normal dose levels are well known [115], even if important individual variations exist [116, 117]. It is a diuretic that stimulates the central nervous system, shortens reaction time, improves alertness, and reduces mental fatigue [118].

It is a cardiac muscle stimulant, a smooth muscle relaxant, and improves physical performance [119], but not up to the point to be considered as a doping agent by the International Olympic Committee (2004). It does not induce addiction [121] and is neither mutagenic nor teratogenic for humans at normal dosages and consumption levels. At excessive levels, other symptoms occur, such as stimulation of gastric acid secretion, increase of heart rate, sweating, nervousness, and sleeplessness. To date, the evidence gathered from many studies "does not suggest that caffeine at present levels of consumption poses a hazard to public health" according to the FDA, which has kept it on the GRAS (Generally Recognized As Safe) list [122].

Other Physiologically Active Substances. An association between coffee consumption and serum cholesterol levels, reported in 1983 [123], is linked with the presence of cafestol (and kahweol) esters in the beverage [124]. The amount present depends on the brewing technique (particularly on fineness of grinding, means of separation of grounds) and is independent of technological parameters (decaffeination, industrial high-temperature extraction). The ester content is high for boiled, French press, and Middle Eastern coffees, where there is no separation of grounds, intermediate in espresso coffee, and negligible in instant and filtered coffees.

In recent years, more and more epidemiologically evident positive effects on human health deriving from a regular coffee consumption have been highlighted [125]. Preventative effects against diabetes [126], hepatic cirrhosis and cancer [127], and Parkinson's disease [128] have been demonstrated by a large number of studies. Regrettably, explanations for the underlying mechanisms are still missing. On the other hand, a chemoprotective effect against colon cancer has been associated with the presence in coffee, beside cafestol and kahweol esters [129], of antioxidants [130] and enhancers of endogenous detoxifying mechanisms [131].

Contaminants. Several types of contaminants are sometimes encountered in coffee. Pesticides [132], present in trace amounts in green

coffee, disappear during storage, roasting and brewing. Paraffins used in the manufacture of jute/sisal bags may contaminate the green beans [133]. Polycyclic hydrocarbons are formed during roasting [134]; if allowed to accumulate in the cold spots of the roaster and of the cooler, where they tend to co-sublime with caffeine, forming whitish deposits, they may constitute a work health hazard. Ochratoxin A, a mycotoxin formed during cherry processing, storage or transport of the beans if moisture is uncontrolled, may be present in trace amounts in commercial coffee products [135], although the substance is partially destroyed during processing [136]. Relatively high levels of ochratoxin A may be present in instant coffees adulterated with husks [137].

Acrylamide, a Maillard product derived by heating sugars with asparagine and present in baked potato products and in bread crust [138], is formed in coffee during the early phases of roasting but largely destroyed during the last ones [139]. Its carcinogenic effects, while observable in rats, have not been evidenced in humans.

1. Definitions

Colloid chemistry involves a number of disciplines, including chemistry, physics, material sciences, and biology.

The particle dimension is the primary parameter that governs the properties of colloidal systems. In a practical sense, any particle that has a linear dimension in the range 10^{-3} to 1 µm can be defined as a colloidal particle. Very small colloidal particles (nanoparticles) have received increasing attention [1].

Colloidal particles can consist of finely subdivided bulk matter or of more or less flexible macromolecules. Particulate colloids are broadly classed as lyophobic (hydrophobic when dispersed in water) or lyophilic (hydrophilic). In addition, micellar solutions can be considered as associative colloids because the micelles formed by association of surface active agents often have colloidal dimensions [2]. This type of colloidal system is not considered here (see → Surfactants, → Laundry Detergents [3]).

Lyophobic and lyophilic colloids differ primarily in the relationship that exists between the colloidal particle and the medium in which it is dispersed. Lyophobic colloidal particles form a two- (or multi-) phase system with the medium, and a phase boundary exists between the particles (*dispersed phase*) and the medium (*continuous phase*) (Table 1).

The interactions between the particles and between the particles and the medium are governed by the structure of the particle surface, in particular the surface charge density and the extent to which it responds to changes in system parameters such as salt concentrations, organic materials, and pH.

Table 1. Classification of colloidal systems

Dispersed phase	Continuous phase	Descriptive names
liquid	gas	aerosol, fog, mist
solid	gas	smoke, aerosol
gas	liquid	foam
liquid	liquid	emulsion, microemulsion
solid	liquid	dispersion, suspension, sol, colloidal solution
gas	solid	solid foam
liquid	solid	solid emulsion, solid foam
solid	solid	solid sol, solid – solid dispersion, alloy

Lyophilic dispersions are true solutions in a thermodynamic sense and are thus one-phase systems. The dispersed and continuous phases are considered as solute and solvent, respectively. The colloidal particles are formed by coils of macromolecules. The macromolecules may be a long thread, more or less stretched, rolled up, or folded. In any case, the coil is open to the dispersion medium, and large parts of the macromolecules are in contact with it. Thus, the shape and size of the coils can change considerably with changes in solvent properties. The system is governed by the laws of macromolecular solutions [4–7].

Lyophobic and lyophilic colloids are also called *electrocratic* and *solvatocratic colloids,* reflecting the important role of electrostatic interactions in the former and of solvent – particle interactions in the latter.

Dispersions of lyophilic colloids form spontaneously when solute and solvent are brought together, as is characteristic of true solutions. In the case of lyophobic colloids, dispersions may or may not be produced spontaneously when finely subdivided matter is added to the dispersion medium. For these reasons, the terms

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a07_341

"reversible" for lyophilic and "irreversible" for lyophobic colloids should be avoided, because they do not describe correctly the behavior of colloidal dispersions.

The dispersed and continuous phases of colloidal dispersions can be solid, liquid, or gaseous. "Aerosol" is used for both liquid/gas and solid/gas dispersions. "Gel" designates solid/liquid dispersions which show a certain stability against mechanical forces [2], [8]. For instance, a test tube containing such a dispersion can be turned over without the dispersion flowing out. Coacervation is the separation of a colloidal dispersion (solid/liquid or liquid/liquid) into a phase with a high contents of the dispersed material (coacervate) and a phase with low content. It is an important step in microencapsulation (→ Microencapsulation, Chap. 4.1.).

2. Colloids in Industrial Uses

Although colloidal dispersions are used in numerous areas of science and technology, very few colloidal systems are produced solely because of their colloidal nature. The scientists in industry use the laws of colloid stability to improve the applicability of materials, to find new fields of applications, or to develop new products. Methods for stabilizing or destabilizing colloidal systems are indispensable for practical applications. For example, it may be necessary to produce a dispersion that is stable for a long period of storage but that destabilizes during application. Thus, it is important to understand the principles that determine stability and instability of colloidal systems.

Areas in which particles of colloidal size are regularly encountered either in stable dispersions or in coagulated or flocculated states are the following [2], [3], [8]:

Chemical Products. Paints, pigments, paper coatings, adhesives, thickening agents, lubricants, catalysts, decolorizing and absorbent materials, and light-sensitive coatings (photography).

Paper Industry and Printing. Fillers, coating, printing inks and pastes, carbonless copying papers, deinking.

Pharmaceutical Industry. Emulsions, microemulsions, cremes, ointments, and absorbing materials.

Materials Science. Powder metallurgy, pelletization, flotation, ore enrichment, alloys, dispersion hardening, superalloys, superplasticity, ceramics, cement, fibers, plastics, additives for reinforcing plastics, tar, bitumen, and native and artificial asphalts.

Oil Recovery. Enhanced oil recovery, emulsification and de-emulsification, and drilling fluids.

Soil Science. Soil engineering, soil stabilization, permeability, adsorption, and ion-exchange processes.

Environmental Science. Fog and smog, aerosols, foams, cloud seeding, water purification, sludges, and supporting materials for biocides and pesticides.

Consumer Products. Dairy products, milk, margarine, beer, waterproofing, cosmetics, cleansing agents, encapsulated products, and additives for foodstuffs.

This list can be supplemented by describing some specific systems of practical importance:

Colloidal Silica. Colloidal aqueous dispersions of silica are easy to prepare by adding sodium silicate (water glass) solutions to dilute hydrochloric acids (silica sols; see → Silica, Chap. 4.) [9], [10]. They are produced on a large scale, and different types of products are available. They are also obtained by dispersing fine-grained silicas such as Aerosil in water or in organic solvents. Silica dispersions are widely used in paints, in pharmaceutical products, and as thickening agents for other aqueous and non-aqueous dispersions.

Oxides and Hydroxides. Titania (TiO_2) is the best white pigment for paints. Aluminum oxides (alumina) and hydroxides (hydrated alumina) are used in many products such as abrasives, toothpastes, papers, plastic materials and rubber (as fillers), and in paints (as pigments, sometimes replacing titania in lower quality products).

Iron oxide pigments are used on a large scale (→ Pigments, Inorganic). A well-known application is the use of γ-Fe_2O_3 (maghemite) as magnetic pigment in magnetic tapes, which requires colloidal particles of distinct shape and sizes (→ Information Storage Materials). They are also used for preparing ferrites (→ Magnetic Materials).

Sulfides and Sulfides. Sulfides of various metals can be obtained as colloidal dispersions. Colloidal arsenic sulfide (As_2S_3) has been known for a long time. The stability of colloidal nickel and cobalt sulfides is familiar to students of analytical chemistry because these sulfides form readily instead of precipitates in the reaction of the metal ions with sulfide ions. Colloidal sulfur with particle sizes of 0.5 – 2 µm, produced by ball milling of sulfur, is used for vulcanization and as fungicide in viniculture and fruit farming.

Silver Iodide and Other Silver Halides. Besides the well-known application of silver halides in light-sensitive coatings (→ Photography), the use of AgI crystals as nuclei in cloud seeding has been studied extensively.

Clays. Clay minerals, major components of bentonites and kaolins, form platelike or sometimes lath-shaped colloidal particles (→ Clays). The annual world use of these natural colloids (excluding China and the former Soviet Union) has grown to more than 10×10^6 t of bentonite, 20×10^6 t of kaolins, and 50×10^6 t or more (exact values are unknown) of common clays. The widespread industrial uses of clays in colloidal dispersions as thixotropic gels or as dry materials have been described extensively [11–15].

Zeolites. Zeolites of almost colloidal particle sizes (1 – 12 µm) are now used as phosphate substitutes in detergents [16].

Colloidal metals are usually obtained by reduction of their salts in solution [8]. Colloidal gold dispersions illustrate the effect of particle size on color. Dispersions of 16-nm particles are orange, those with 41-nm particles are red, and those with 98-nm particles are violet with a yellow Tyndall effect of the scattered light [10], [17]. Some unsupported metals in colloidal dispersion are used as catalysts.

Alkali and alkaline earth metal colloids are available in organic solvents (Na in benzene; Ca, Sr, and Ba in propyl and isopropyl alcohol). Blue rock salt (sodium chloride) contains sodium in colloidal dispersion.

Semiconductor Colloids. Research in semiconductor colloids is developing in two directions: (1) preparation of particles with narrow size distribution and regular shape and investigation of their properties, and (2) their self-assembly into new materials and devices [18], [19].

The quantum size effect of colloidal semiconductor particles (ca. 2 – 4 nm in diameter) was first recognized by Brus. A nanoparticle represents a three-dimensional potential well for the charge carriers that are generated by absorption of a photon. The consequence is a blue shift of the threshold of absorption and fluorescence band with decreasing particle size. For semiconductors, this blue shift can be very pronounced [20]. The color of Cd_3P_2 particles changes from black (coarse particles) to brown (3 nm diameter), red, yellow, and white (1.5 nm)

Latices. Polymer particles of different structure and surface morphology (Fig. 1) are formed by emulsion, dispersion, and suspension polymerization [8, Chap. 6].

Figure 1. Types of latex particles [8]
A) Monomers; B) "Classical" particles; C) Bristly latices (surface with adsorbed emulsifier molecules); D) Hairy latices; E) Core – shell particles; F) Polymer coils

The particles usually carry negative surface charges, although positively charged latices and amphoteric forms (with both positive and negative surface charges) are also available.

Latices are used in many applications, for instance as binders in paints, for paper filling, coating, impregnation, diving equipment, latex, and latex foam [21].

Hydrophilic Colloids. Typical examples are gelatin, pectins, alginates, alginic acids, and proteins. Synthetic products are, for instance, polyacrylic acid and its salts. Alginates, gelatin, and pectins are used as thickening and thixotropic agents, emulsifiers for pharmaceutical products, cosmetics, and in the food-processing industry.

3. Preparation of Colloidal Particles

Colloidal particles are prepared by dispersion of larger particles or by condensation of atoms, ions, or molecules [2], [8], [22].

Dispersion Methods. Dispersion of larger particles into particles of colloidal size often requires high mechanical forces and can only be attained in high-energy mills such as colloid mills. Cavitation processes in the solvent [23] during milling promote particle size reduction [8, Chap. 5]. However, agglomeration processes become effective at high inputs of mechanical energy, so that the particle size reaches a lower limit. On the other hand, the forces in high-energy mills are so strong that solid materials can be alloyed like iron and silver which usually do not form alloys. Mechanical alloying is an important technical process, for instance for hardening of metals by dispersed oxides (dispersion hardening).

During particle size reduction new surfaces are created which must be covered by sufficient stabilizing agent to prevent reaggregation. Therefore, more powerful equipment which yields smaller particle sizes often requires higher amounts of stabilizers.

In the early 1900s Bredig and Svedberg studied the scattering of metals by arcs formed between two metal electrodes within a solvent. A modern version is ion beam sputtering, which has become important for preparing nanocrystalline materials.

Dispersion of a liquid phase into an other liquid phase (emulsification) is much more easier, as everyone knows from the preparation of mayonnaise. Nevertheless, technical preparation of emulsions often needs considerable amounts of energy. In all cases a careful selection of effective emulsifiers or emulsifier mixtures is imperative.

Condensation Reactions. A well-known condensation method for preparing colloidal dispersions is the reduction of nobel metal salts in aqueous or nonaqueous solvents [8], [24]. Another simple method is precipitation of low-solubilty compounds from solution. In many cases particles with broad size distributions and irregular shape are obtained. Precipitation from homogeneous systems is of great advantage. The starting system is a homogeneous solution, and precipitation is slowly initiated by hydrolytic reactions or the slow decomposition of complexes. Often, a precursor compound is dissolved in organic solvents, then slowly hydrolyzed by addition of water [8, Chap. 5]. A variety of monodisperse colloidal particles of different sizes and shapes were prepared by Matijević et al. [8, Chap. 5], [22], [25–28].

Polymer colloids are prepared by emulsion, dispersion, and suspension polymerization. Latices are obtained by emulsion polymerization (with or without emulsifier) of styrene, butadiene/styrol, acrylamide, *N*-isopropylacrylamide, etc. They are usually obtained as spherical particles, but many other forms and surface morphologies can also be produced [8, Chap. 6], [21], [29].

An example for gas phase reactions is the flame hydrolysis of $SiCl_4$ and $TiCl_4$ forming finely dispersed silica (→ Silica, Chap. 6.) and titania. Chemical vapor deposition can be used to coat preformed particles.

A problem in the preparation of colloidal particles is the need to stop particle growth when the desired size is attained. Preparation in confined systems provides advantages. One method consists of nucleation and growth of the particles within the dispersed water of microemulsions [8, Chap. 5], [30–32] or within the water cores of reverse micelles [33], [34]. Different types of nanosized colloidal particles were prepared in block copolymer micelles [35–37]. The use of templating polymer gels is an other way to produce porous materials, particles of unusal shape, and to stabilize less stable modifications [38], [39].

Dékány et al. [40], [41] described the production of nanoparticles in the confined spaces between clay mineral particles. Gold clusters and colloidal gold particles were formed in alumina nanotubes [42].

Peptization. In several cases the particles are of colloidal size but are aggregated. Colloidal dispersions are then prepared by peptization. The methods required for successful peptization depend on the chemical nature of the aggregated particles.

4. Properties of Colloidal Systems

Shape and Size of Colloidal Particles. Many colloids form spherical particles (e.g., silica, alumina, titania, metals, and latices), but particles with other shapes can also be obtained. Particle anisometry affects the colloid stability, particularly, when both positive and negative surface charges are present, as in clay colloids.

The shape of the particles can be determined by transmission or raster electron microscopy. Difficulty arises with smectitic clay minerals, which often form broad undulating mosaic sheets, making individual particles barely discernible. Modern transmission electron microscopy, however, allows the observation of very thin particles [43]. The jet-freezing technique allows the imaging of particles dispersed in the solvent phase [44] or of the microstructure of microemulsions [45]. More recently, colloidal particles and aggregation processes in aqueous media were made visible in situ by X-ray microscopy [46–49].

Colloidally dispersed particles can be monodisperse or polydisperse. The size distribution can be narrow or wide, uniform or bimodal, or even more complex [10]. Modern preparative techniques can produce particles with very narrow size distribution (monodisperse systems).

In the case of particle size distributions or anisometric particles [50], [51], the different experimental methods yield different types of average diameters. The light-scattering mean value is larger than the volume-average mean diameter, which in turn is larger than the number average diameter [8, Chap. 8].

The particle size can be obtained from electron micrographs, by light scattering (turbidity measurement, photon correlation spectroscopy, dynamic light scattering), sedimentation methods, cuvette and disk centrifuge photosedimentation, and streaming methods (Coulter counter, capillary fractionation, field flow fractionation) [8, Chap. 8], [52–54].

Shape, particle size, and size distribution are very important for highly concentrated dispersions like paper coatings and ceramic masses. The desired fluidity of such dispersions not only requires the appropriate chemical treatment but also careful selection of particle sizes and size distribution. A broader size distribution is advantageous for obtaining a lower viscosity [8, Chap. 12], [55], [56]

Light scattering [2], [10], [53], [57] is theoretically complicated, but rigorous solutions of scattering patterns are available. The use of dynamic light scattering for particle size determination is very common. However, the data are often uncritically accepted. Polydispersity cannot be recognized in every case. As the scattered light intensity is proportional to d^6, the presence of even small amounts of larger particles strongly influences the average particle diameter [8, Chap. 8], [52–54], [58].

The Tyndall effect is a well known light scattering phenomenon. When the dispersion is viewed against the light, it appears to be perfectly transparent, but when viewed from the side, the dispersion seems to be turbid. This effect is demonstrated by colloidal sulfur. Addition of dilute hydrochloric acid to sodium thiosulfate solution precipitates colloidal particles of sulfur, which grow in size with time [10]. When the dispersion is viewed directly in white light, the initial white color becomes yellow, then orange, then red, and finally dark brown. However, if the illuminated dispersion is viewed from the side, it looks turbid, milky, and the optical density increases with time.

Stability. Dispersions of lyophobic colloids may be stable for weeks, months or years, despite their inherent thermodynamic instability. Such dispersions are said to be *peptized.* These dispersions are destabilized by the addition of salts, and when specific threshold concentrations are exceeded, the dispersion coagulates. The critical coagulation concentrations c_K are essentially dependent on the valency of the ion that is charged oppositely to the particle surface (counterion). This fact was established in the early days of colloid science by the Schulze – Hardy rule. The chemical nature of the counterion is far less important, as are the valency and nature of the ion with the same sign of charge as the particle (co-ion), if there is no chemical interaction. Variations of c_K with the nature of the counterions are observable, but are small compared with the changes due to different valencies.

According to the Hardy – Schulze rule the ratio of c_K values is

$$c_K(1) : c_K(2) : c_K(3) = 1 : x : x^2$$

where x varies from 1/40 to 1/30. $c_K(i)$ is the critical coagulation concentration of counterions with valency i. One can also write

$$c_K(1) = (30-40)\, c_K(2) = (900-1600)\, c_K(3)$$

The experimental c_K values of monovalent cations range from 25 to 500 mmol/L. For di- and trivalent counterions, c_K values of 0.1 – 10 mmol/L and 0.01 – 1 mmol/L, respectively, are typical [8, Chap. 3].

Hence, di- or trivalent counterions are preferred for coagulation of peptized dispersions. In practice, aluminum or iron(III) salts are used.

Within the series of alkali cations as counterions, the c_K decreases in the order (Hofmeister series)

$$Li^+ > Na^+ > K^+ > NH_4^+ > Cs^+ > Rb^+$$

and for anions as monovalent counterions

$$SCN^- > I^- > NO_3^- > Br^- > Cl^- > F^-$$

Hence, a negative AgI dispersion is coagulated by 165 mmol/L of $LiNO_3$ and 126 mmol/L of $RbNO_3$, a positive Al_2O_3 dispersion by 60 mmol/L of KNO_3 and 46 mmol/L of KCl (see also Fig. 21).

Dispersions of lyophobic colloids are also affected by addition of polymers (see page 27).

Peptization and Repeptization. Colloidal dispersions are formed spontaneously when certain finely subdivided materials are added to a liquid under suitable conditions. For instance, fine grained quartz, amorphous silica, or sodium clays peptize by simply shaking the powders with water. Other materials require small quantities of specific electrolytes for peptization [Ag^+ or I^- ions for AgI, SH^- ions for sulfides, H^+ or OH^- ions for oxides and hydroxides (see Chapter 6)].

Dispersions that have been coagulated by salts may or may not repeptize by removing the salt, for instance by simply washing with the solvent (usually water) or by dialysis. Generally, colloids coagulated with di- or trivalent counterions are more difficult to redisperse than colloids coagulated with monovalent ions. An exchange of the multivalent ions by sodium ions is often imperative for repeptization. This is particularly true for clay minerals that do not peptize in the presence of calcium ions and in the absence of sodium ions. The Ca/Na ratio is thus a very important factor in practical uses of clays. On an industrial scale clays and clay minerals are peptized by addition of sodium ions (in amounts similar to the cation-exchange capacity), mostly in form of soda (soda-activated or alkali-activated clays) [8], [14], [59].

In other cases the pH must be changed (see page 9, page 23 and Chap. 3). Surfactants can also be used as dispersants. One of the most important methods is the use of protective colloids. These are macromolecular compounds that are adsorbed on the particles and give them enhanced surface charge density or stabilize them sterically (see page 17). Steric stabilization is often needed in ceramics [60], [61], and drilling fluids [14], [62], [63].

Particles flocculated from sterically stabilized dispersions are repeptized by changing the solvency of the solvent or, in some cases, by changing the temperature (see page 17).

In many cases, repeptization is prevented by secondary reactions between the coagulated particles (aging processes). The particles can grow together or may undergo structural changes that render repeptization difficult or impossible.

Aggregation. The theory of colloid stability (Chap. 5) pertains to the initial states of aggregation. The subsequent steps and the way in which the particles aggregate and settle to form a sediment are very important in practical applications [8, Chap. 12]. Limiting cases are illustrated in Figure 2. Sediments that are produced from highly peptized dispersions are compact and difficult to stir. Such sediments form when particles settle slowly from well-peptized dispersions at low salt concentrations (below c_K), on standing for longer periods, by slow evaporation of the solvent, or by filtration. At higher salt concentrations, if the dispersion coagulates more rapidly, voluminous sediments are formed that are easy to redisperse by stirring. Types of sediments intermediate between the examples shown in Figure 2 can be obtained by selecting appropriate experimental conditions, for instance, by carefully adjusting the salt (or polymer) concentration or by changing pH (see page 23) or the type of counterion. Coagulation with divalent counterions often favors formation of voluminous sediments.

Figure 2. Sediments from peptized and coagulated or flocculated dispersions
a) Spherical particles
A) Dense sediment with repulsive interaction between the particles; B) Voluminous sediment with attractive interaction between the particles.
b) Platelike particles
C) Dense sediment with repulsive interactions between the particles; D) Band-type structure with attractive face/face interactions between the particles; E) House-of-cards structure with attractive edge/face interactions between the particles

Compact sediments form if the interaction between the particles is repulsive. Such particles are able to move, sliding and rolling past each other as they settle to form a closely packed sediment, but without coming into actual contact because of their mutual repulsion.

With sufficiently monodisperse spherical particles of latices [65], [66] and various other materials, for instance, silica [9], [67], the particles can settle in regular arrays which give Bragg reflections with light, similar to those from crystals of closely packed spheres with X-rays [64], [68]. Due to the presence of ordered domains, the dispersion shows a pronounced play of color when viewed in white light at different angles (iridescence) [67], [69]. The name *colloidal crystals* is sometimes used for these highly ordered aggregates [70].

If conditions in solution are such that the particle – particle interaction becomes attractive, the particles aggregate to some extent in the dispersion. The haphazardly formed flocs settle and pile up at the bottom of the vessel to form a voluminous sediment. The large voids between the particles are filled with solvent. Figure 3 shows different types of voluminous aggregates. Spherical particles form a three-dimensional network consisting of strings of particles tied together like strings of beads. Depending on the experimental conditions and the charge distribution, platelike particles aggregate to band-type structures (face/face contacts) or houses of cards (edge/face contacts). The different types of aggregation are very important in practical uses of kaolins, bentonites, and clays [8, Chap. 12], [71–73].

Figure 3. Network structure of A) platelike particles (house-of-cards), B) lath-shaped, and C) spherical particles

The formation of a stable voluminous network requires attractive forces at the interparticle contact sites. These are the same electrostatic

forces that cause colloidal particles to coagulate and that are attractive only in the presence of salt (see page 13). The volume of the aggregate can increase with an increase in salt concentration above the critical coagulation concentration because of the enhanced attractive forces. Divalent counterions strengthen the forces at the contact points which may increase the stability and volume of the network. The salt concentrations required are distinctly lower than those for monovalent counterions. If the attractive forces are too strong, the volume-filling network of particles contracts and fragments, and distinct aggregates form.

Amorphous silica like Aerosil form networks (Fig. 3) in many water-immiscible or organic solvents. The particles are held together by hydrogen bonds and by bridges of water. This type of network formation is used practically for thickening organic liquids [8, Chap. 12].

Finally, the term *gel* warrants discussion. It is used as a counterpart to *sol* (sol: peptized colloid; gel: coagulated colloid). However, coagulated dispersions do not usually have those properties that one associates with "gel". Thus, *gel* may be used for voluminous network structures that possess a certain degree of stiffness (*gel strength*). Many hydrophobic colloids (SiO_2 and Al_2O_3) form gels under certain conditions. The voluminous band-type and house-of-cards structures of the clay minerals show this property very clearly. Gelation is a general phenomenon of lyophilic colloids [5].

Many practical applications are very sensitive to the stability of the dispersion and the type of aggregates formed. The delicate adjustment of the stability conditions in paints is an example. The dispersed pigments in paints settle slowly during standing. To avoid compact sediments, the suspension must be held in some kind of flocculated condition, but the stability parameters must be adjusted so that the paint can be applied properly. On the other hand, the formation of thin surface coatings by sedimentation or electrodeposition (insulating films and fluorescent coatings) demands compact sediments. Again, the compactness is adjusted by varying the stability of the suspension from which the coating is obtained.

The widespread uses of clays are based on their ability to form all types of aqueous and nonaqueous colloidal systems ranging from highly fluid dispersions to stiff gels with pronounced thixotropy.

Filterability. The finely subdivided solid matter of colloidal dispersions cannot be separated from the dispersion medium by filtration through ususal filters because of the small particle size. Filter materials are now available with pore diameters as small as a few nanometers, so that larger colloidal particles can be retained (colloidal filtration [74], [75]).

The contrasting behavior of dispersions of sodium smectite (→ Clays) is noteworthy. These dispersions are difficult to filter, even through filters with large pores. A thin filter cake forms at the very beginning of filtration and makes the filter rather impermeable. The clay platelets become aggregated parallel to each other and form a dense sediment. For filtration, the dispersion must be held in a coagulated or flocculated state, for instance by adding Ca^{2+} ions, organic solvents such as ethanol, or small amounts of polymeric materials. Flocculation by polyanions is widely used in the processing of clays [14], [62]. On the other hand, engineering work takes advantage of the formation of almost impermeable clay films to reduce the permeability of rocks and soils. This "plastering" is also important in drilling operations [11], [14], [62].

Sedimentation. When spherical colloidal particles in dilute dispersions move independently, they settle under the influence of gravity [2], [10], [57], [74–77]. The particle falls through a distance h in time t (Fig. 4)

$$t = 18\eta_0 / (\varrho - \varrho_0)\, g \cdot h / d^2 \qquad (1)$$

(ϱ, d: density and diameter of the particle; ϱ_0, η_0: density and viscosity of the dispersion medium, g: gravitational acceleration: 9.81 m/s^2).

In water, 10-µm quartz particles ($\varrho - \varrho_0 = 1.65$ g/cm^3, $\eta_0 = 1.001 \times 10^{-2}$ g cm^{-1}s^{-1}, 20 °C) need $t = 18$ min 34 s to fall a distance of 10 cm, 1-µm particles need $t = 30$ h and 57 min. With too small particles (< 1 µm for quartz or clay minerals) the sedimentation time becomes so long that sedimentation is disturbed by Brownian motion. A centrifugal field must be used for sedimentation of such particles. The gravitational acceleration in the Stokes equation (Eq. 1)

is replaced by the radial acceleration, which can be increased to ca. $10^3\,g$. The particles then fall the distance $h = r - r_0$ (Fig. 4) in the time t [78]:

$$t = \frac{K_c}{d^2 U^2} \ln r/r_0 \quad \text{(in seconds)} \tag{2}$$

where $K_c = 18\,\eta_0 \cdot 60^2/(\varrho - \varrho_0)\,4\,\pi^2$ with $U = \text{rpm}$ (rotations $\cdot$ min^{-1}). For $U = 5000$, $r = 12$ cm, $r_0 = 10$ cm, the sedimentation times of 0.1-µm and 0.01-µm quartz particles in water at 20 °C are 12 min 7 s and 20 h 12 min.

Figure 4. Sedimentation under gravity (A) and under centrifugal forces (B)

The high centrifugal acceleration required for sedimentation of particles < 0.01 µm in diameter in reasonable times can only be realized in ultracentrifuges, in which the radial acceleration can easily be increased to $10^5\,g$. This instrument is used extensively for characterization and determination of the molecular mass of macromolecular colloids, particularly those of biological origin such as proteins, nucleic acids, and viruses.

When the particles are not spherical, the application of the above formulas leads to *Stokes equivalent diameters* [50], [51]. In the sedimentation of nonspherical particles, the friction factor f is larger than that for spherical particles ($f_0 = 3\,\pi\,\eta_0\,d$), and the viscous resistance is increased. Thus the particles settle more slowly than spherical particles of the same mass. The same effect is produced by particle solvation. A particle containing a given volume of dry material has its smallest possible friction factor if it is an unsolvated sphere [10], [57], [76].

Sedimentation under gravity and in the centrifugal field finds practical application in separating particles into fractions of different sizes and for determination of particle size distributions. For commercial uses, the fractionation is often confined to the removal of particles of too large or too small dimensions. Fractionation by sedimentation is applied particularly in processing clay minerals and pigments. Experimental details for such laboratory techniques as fractionation and determination of particle size distribution have been described [8, Chap. 6], [78]. Several "particle size analyzers" are available, but manual control experiments are recommended.

Rheological Phenomena. In dilute colloidal systems the particles move independently of each other and the system behaves as a Newtonian fluid [2]. With increasing particle concentration, a gradual transition from Newtonian to plastic or pseudoplastic behavior is generally observed [10], [57], [76], [79]. The transition occurs when mutual interactions between the particles become significant. This can be illustrated by dispersions of silica (Aerosil) [79]. At pH 3 the dispersion exhibits Newtonian flow up to silica concentrations of ca. 10 wt %, above which shear thickening at high shear rates and increasing hysteresis effects are observed. At pH 9, there is a gradual transition from Newtonian to pseudoplastic flow as the silica content is increased above 5 wt %. Figure 5 shows a plot of the plastic viscosity (obtained from the slope of the linear portion of the shear rate – shear stress curves) at different pH values as a function of particle concentration. Near pH 7 the viscosity increases strongly above a particle concentration of 8 wt %. At pH 9 and pH 3, higher particle concentrations are required to obtain dispersions of high viscosity.

Figure 5. Plastic viscosity of silica dispersions at different pH as a function of solid content [79]

Figure 5 demonstrates the effect of particle – particle interactions on rheological

phenomena. At low pH the surface charge density of the silica particles is low (see Chapter 6), and the particles aggregate to dense flocs [80] with Newtonian flow behavior. Because of the low surface charge density, the concentration of the particles can be increased considerably without significant viscosity changes. At high pH, the increased negative surface charge density and electrostatic repulsion prevent the particles from forming large dense flocs so that the number of moving particles and small aggregates is increased. This effect and the stronger electrostatic interaction lead to higher viscosities than those at pH 3. In the neutral range, the particles interact strongly through hydrogen bonds and form network structures with considerable increase in viscosity. The electrostatic repulsion between the particles is too weak to disrupt the network but strong enough to prevent the formation of dense flocs as at pH 3.

It should be noted that the viscosity of silica dispersions depends on the nature of the silica (fumed silica such as Aerosil and precipitated silica such as Kieselgel) and the dispersing procedure (ultrasonication or not [80]).

The dependence of the viscosity of colloidal silica dispersions on concentration, pH, and electrolyte or polymer addition is widely used in practical applications. Fumed silica serves as a thickening and gelling agent for aqueous and nonaqueous liquids. In polar solvents the thickening is optimal in the neutral pH range. The thickening efficiency of silica can be improved by additives that stabilize the network structure. Suitable additives for dispersions in nonpolar solvents are water, ethylene glycol, or ethylene diamine [8, Chap. 12].

Clays find widespread applications because of their special rheological properties and pronounced thixotropic behavior. Thixotropy is the property of dispersed systems to become more fluid (lower viscosity) under the influence of mechanical forces (stirring, shaking, shearing) and to regain the higher viscosity at rest. It is caused by fragmentation of the network structure by the mechanical forces. At rest, these fragments are pushed into new contact positions by the Brownian motion of the solvent particles and reaggregate to the volume-filling network. Practical applications of thixotropy are found in tomato ketchup, paints, paper coating, drilling fluids, and civil engineering (slurry walling, underground sealing) [2], [8, Chap. 12], [11], [12], [14] [62], [81].

Electrokinetic phenomena are observed when two phases move relative to each other under the influence of an electric field. Electrophoresis describes the motion of charged particles or droplets in an applied electric field (for other electrokinetic phenomena see [8], [10], [53], [57], [76], [82]). A thin layer of liquid adheres to the particle or droplet surface so that the shearing plane is located anywhere in the liquid. The potential at the shearing plane is called the electrokinetic or zeta potential ζ. Because of the unknown distance of the shearing plane from the particle surface, electrokinetic phenomena are often difficult to interpret.

The velocity u of a particle in an electric field E depends on the dimensions of the particle and the atmosphere of counterions around it, i.e. on $\varkappa a$ (see page 13; for details see [8], [53], [57], [82]): $\varkappa a \ll 1$: small particles with large diffuse ionic layers:

$$u = 2\varepsilon\varepsilon_0\zeta E/(3\eta_0)\ \text{(Hückel – Onsager equation)} \quad (3)$$

(ε: relative dielectric constant, $\varepsilon_0 = 8.854 \cdot 10^{-12}\,\mathrm{AsV^{-1}m^{-1}}$, E: applied electric field strength, η_0: viscosity of the dispersion medium). $\varkappa a \gg 1$: large particles with diffuse ionic layers much thinner than the particle radius

$$u = \varepsilon\varepsilon_0\zeta E/\eta_0 \quad (4)$$

(Helmholtz – Smoluchowski equation)

$\varkappa a \approx 1$

$$u = 2\varepsilon\varepsilon_0\zeta E/3\eta_0 \cdot f(\varkappa a)\ \text{(Henry equation)} \quad (5)$$

[$f(\varkappa a)$ [76], [82] $f(\varkappa a) = 1$ for $\log(\varkappa a) \leq -1$, $f(\varkappa a) = 1.5$ for $\log(\varkappa a) \geq 3$; but note a different variation for metal colloids]. Table 2 illustrates the applicability of the Equations (3) – (5) for different particle diameters and electrolyte concentrations. Usually particles between 0.1 µm and 10 µm are observable in electrophoretic cells so that the Smoluchowsky and Henry equations are more applicable than the Hückel equation.

Corrections to these equations can be made to account for the particle – particle interactions in dispersions that contain more than 5 wt % solid particles [82, Chap. 4]. In such dispersions the

Table 2. Applicability of the Helmholtz – Smoluchowski, Henry, and Hückel – Onsager equations (Eqs. 3 – 5) for determining zeta potentials

Normality of solution	Approximate particle diameter (nm) for which the equations are valid		
	Helmholtz – Smoluchowski	Henry	Hückel – Onsager
1	≥ 80	0 – 80	–
0.1	≥ 200	0 – 200	–
0.01	≥ 800	1 – 800	0 – 1
0.001	≥ 1800	2 – 1800	0 – 2
0.0001	≥ 8000	10 – 8000	0 – 10
0.00001	$\geq 16\,000$	20 – 16 000	0 – 20

mobility of the particles is reduced, and too small zeta potentials would be obtained without the corrections. Further corrections are needed for electrophoretic retardation and relaxation [83–85]. Since the counterions with their hydration shells tend to move in an opposite direction from the particles, the movement of the particles is retarded. Furthermore the double layer must be constantly restored in front of the particle and dispersed behind the particle. This restoration takes a finite time (relaxation). The double layer is therefore shifted somewhat with respect to the particle and a field is created that opposes the applied electric field and reduces the mobility. For practical purposes, the corrections can be neglected for low particle concentrations and small zeta potentials. Recently, the influence of surface conduction on the mobility has become evident [8, Chap. 10], [82, Chap. 4], [86].

The electokinetic mobility is an important quantity in colloid chemistry and is a fundamental property of colloidal particles. It gives important information such as the sign of the surface charge, the way in which the charge changes when experimental parameters are changed, and the conditions that establish the isoelectric point. It responds to the addition of inorganic compounds and monomeric and polymeric organic materials, thus providing information about the interaction of the colloid particles with these materials. Zeta potential measurements can also be used for some kinds of quality control. For example, commercial TiO_2 pigments, both anatase and rutile, can exhibit isoelectric points between pH 1 and 7, depending on the way they have been prepared. The variation is caused by adsorption of anions, mainly sulfate and phosphate anions, which are introduced during industrial production. The isoelectric point of pure TiO_2 (both modifications) is near pH 6.9. Measurements of zeta potentials can also be used to obtain information on the flotability of minerals in flotation processes [10], [87].

The electrokinetic mobility usually is measured by microelectrophoresis and laser-doppler electrophoresis (commercial instruments are available). In the 1990s the instrumentation and theory of the electroacoustic characterization of colloidal dispersions and emulsions made great strides. An important advantage is that the particle dynamic mobility can be determined in dispersions of essentially any concentration above about 1 wt %. Apparatus is available to measure particle sizes in the range 0.1 – 10 µm and the zeta potential of particles down to nanometer dimensions [88]. The moving boundary method [76], [89–91] is simple and does not require large and expensive instrumentation. Horn and Ditter [92] describe a self-made laser interferometer for mobility measurements of pigment particles in organic solvents.

In most commercial instruments the zeta potential is calculated from the mobility by means of the Helmholtz – Smoluchowski equation (Eq. 4). However, conversion of mobility data to zeta potentials is not without arbitrariness [8]. It is recommended to report the electrokinetic mobility instead of possibly false zeta potentials.

5. Colloid Stability

Origin of Colloid Stability. No finely subdivided material dispersed in a continuous phase is ever stable in a thermodynamic sense. The dispersed particles or droplets tend to reduce the large interfacial area by aggregation to a continuous phase. The coarsening process may be slow, but it is inexorable. If special stabilization mechanisms are absent, the particles or droplets aggregate spontaneously (Fig. 6). Two mecha-

nisms are known for stabilizing the colloidal state, electrostatic stabilization and steric stabilization. Electrostatic stabilization occurs when the surface of the particle or droplet carries an electric charge. The particles are surrounded by atmospheres of counterions and an electrostatic repulsion is created between these atmospheres. As long as the repulsion V_R exceeds the van der Waals attraction V_A between the particles, the colloidal dispersion is stable. When the van der Waals attraction overcomes the electrostatic repulsion, the system becomes unstable. This occurs when the concentration of salts added to the dispersion exceeds a critical value.

Figure 6. Electrostatic (A) and steric (B) stabilization of colloidal dispersions and emulsions

The dispersion also becomes unstable when the surface charge disappears. This occurs when the concentration of protons or other potential-determining ions (see Chapter 6) is changed or when counterions are introduced that are strongly absorbed (see Chapter 6).

Long-chain molecules or macromolecules adhering to the particle surface cause steric stabilization. Envelopes of organic matter around the particles prevent the particles from aggregating. Such dispersions are often difficult to destabilize because salts exert little influence. Destabilization can be achieved by changing the temperature or the quality of the solvent, thus changing the polymer – solvent interaction (see page 17).

Liquid particles in emulsions have the same kinds of interactions as solid colloidal particles. They can be stabilized electrically by surface charges or sterically by macromolecules (→ Emulsions). Important emulsifiers are nonionic surfactants like alkyl poly(ethylene oxides). Ionic surfactants are used in combination with nonionic surfactants [8, Chap. 7].

Stabilization by solid particles is one of the pathways that lead to new types of emulsions [93–95].

DLVO Theory: the Ionic Layer. The DLVO theory (DLVO: Derjaguin, Landau, Verwey, and Overbeek [8], [10], [53], [57], [76], [82], [96–99]) describes the interplay between electrostatic repulsion and van der Waals attraction. The theory may be illustrated for particles with a negative surface charge density (σ_0), dispersed in a continuous liquid phase of dielectric constant ε, for instance water with $\varepsilon = 78.5$ (25 °C). An electric potential $\psi = f(x)$ then exists that decays from $\psi = \psi_0$ at $x = 0$ (ψ_0 = surface potential) to $\psi = 0$ far away from the surface ($x \to \infty$) (Fig. 7 and Fig. 19). A cation (counterion) at position x is then attracted by the surface, but the electrostatic force is counteracted by the thermal motion of the ions, and the distribution of the counterions is determined by the Boltzmann equation. The concentration of counterions, therefore, decreases from a value at $x = 0$ to the bulk concentration at $x \to \infty$ (Fig. 8). Anions (co-ions) are repelled from the surface.

The counterions and the co-ions are not arranged in a distinct pattern on the particle surface but are distributed within an atmosphere surrounding the particle. The dimension of this diffuse (or Gouy – Chapman) layer can be substantial (Fig. 8). The thickness of the diffuse layer is given by $1/\varkappa$, the Debye – Hückel length. The quantity $\varkappa$ contains a cluster of

constants (concentration c_i (mol/m^3) and valencies v_i of the ions, $F = 96\,485.29$ A s mol^{-1}, $\varepsilon_0 = 8.854 \times 10^{-12}$ A s V^{-1} m^{-1}):

$$\varkappa^2 = F^2 \sum v_i^2 c_i / (\varepsilon\varepsilon_0 RT) \tag{6a}$$

When only one type of salt is present with $v^+ = v^- = v$ (for instance: NaCl, KNO_3, $MgSO_4$) $\sum v_i^2 c_i = 2v^2 c$ and

$$\varkappa^2 = 2F^2 v^2 c / (\varepsilon\varepsilon_0 RT) \tag{6b}$$

The reciprocal length $\varkappa$ is of general importance and is widely used in colloid science instead of the concentration. For water ($\varepsilon = 78.5$ at 25 °C) one obtains with c expressed in mol/L:

$$\varkappa^2 = 32.87 \times 10^6 v\sqrt{c}\ \mathrm{cm}^{-1} \tag{6c}$$

For 10^{-5}, 10^{-3}, and 10^{-1} mol/L solutions, $\varkappa$ is ca. 10^5, 10^6, and 10^7 cm^{-1}, respectively ($v = 1$). The reciprocal value $1/\varkappa$ is generally considered a measure of the thickness of the diffuse ionic layer. For large or platelike particles the potential is reduced to $\psi_0/e = 0.37\,\psi_0$ at the distance $x = 1/\varkappa$ from the surface. The ionic layer extends further into the continuous phase, and ψ becomes $0.01\,\psi_0$ at $x = 4.6 \cdot 1/\varkappa$.

The extension of the ionic layer is very sensitive to salt addition. This is seen from the variation of $1/\varkappa$ with the salt concentration (Eq. 6 c). As the concentration of salt ($v = 1$) is increased by a factor of 10 or 100, the thickness of the ionic layer $1/\varkappa$ is reduced by the factors 0.32 and 0.1, respectively. At a salt concentration $c = 10^{-5}$ mol/L, the thickness of the ionic layer is $1/\varkappa = 100$ nm. Increasing the concentration to 10^{-3} or 10^{-1} mol/L compresses the double layer to $1/\varkappa = 10$ or $1/\varkappa = 1$ nm.

Polyvalent ions exert a similar effect (Eq. 6 c). Di- and trivalent ions compress the diffuse layer thickness by a factor of 2 and 3, respectively.

DLVO Theory: Electrostatic Repulsion and van der Waals Attraction. The compression of the double layer has dramatic effects on the stability of colloidal dispersions. At low electrolyte concentration, the atmosphere of counterions is extended, and particles are widely separated. Higher electrolyte concentrations compress the diffuse layer, and the particles approach more closely (Fig. 9). At $\varkappa = 10^7$ ($c = 10^{-1}$ mol/L, $v = 1$) the particles can approach to ca. 5 nm until they "feel" the mutual repulsion.

Figure 7. Diffuse ionic layers around and between spherical and platelike colloidal particles

Figure 8. Concentration of monovalent counterions (n^+) and co-ions (n^-) around platelike particles or large spheres at different electrolyte concentrations (surface potential ≈ 50 mV). $\varkappa$ in cm^{-1}

The electrostatic repulsion between two particles can be calculated by the approximation:

$$V_\mathrm{R} = 32\pi a\varepsilon\varepsilon_0 \left(RT/(vF)\right)^2 \gamma^2 e^{-\varkappa H}\ \mathrm{J} \tag{7}$$

where H is the nearest distance between two particles (Fig. 7), and the expression for γ is

$$\gamma = \left(e^{z/2} - 1\right) / \left(e^{z/2} + 1\right)$$
$$\text{with } z = vF\psi_0/(RT) \tag{8}$$

It should be noted that γ approaches 1 at higher surface potentials ($\psi_0 \geq 150$ mV). The electrostatic repulsion then becomes almost independent of the surface potential.

Figure 9. Electrostatic repulsion V_R between spherical particles (radius 100 nm) at different electrolyte concentrations, $v = v^- = 1$, surface potential: ≈ 50 and 100 mV, H: see Fig.7
a) $z = 2$ ($\psi_0 \approx 50$ mV), $\varkappa = 10^5$ cm^{-1} (10^{-5} mol/L);
b) $z = 4$ ($\psi_0 \approx 100$ mV), $\varkappa = 10^6$ cm^{-1} (10^{-3} mol/L);
c) $z = 2$ ($\psi_0 \approx 50$ mV), $\varkappa = 10^6$ cm^{-1} (10^{-3} mol/L);
d) $z = 2$ ($\psi_0 \approx 50$ mV), $\varkappa = 10^7$ cm^{-1} (10^{-1} mol/L)

The van der Waals attraction is nearly independent of the salt concentration. A good approximation for spherical particles is

$$V_A = -\frac{A}{12}\left(\frac{L}{H} + 2\ln\frac{H}{L}\right) \tag{9}$$

with $L = a + 0.75\,H$ [100]. The Hamaker constant A is dependent on the chemical composition of the particles. Typical values for aqueous dispersions follow [8], [101], [102]:

Metals:
$A \approx (15-30) \times 10^{-20}$ J
Oxides, silicates:
$A \approx (1-5) \times 10^{-20}$ J
Inorganic salts:
$A \approx (0.3-5) \times 10^{-20}$ J
Polymers (latices):
$A \approx (0.3-1.4) \times 10^{-20}$ J

A more precise value for latices has been reported [103].

Figure 10. Schematic representation of the interactions between colloidal particles
V_R electrostatic repulsion; V_A van der Waals attraction; V_B Born repulsion

The van der Waals attraction decays more rapidly with particle distance than does the double layer repulsion. It becomes operative only when the double layer is sufficiently compressed that the particle can approach closely. Under these conditions the attraction overcomes the double layer repulsion, and the particles attract each other; thus coagulation is initiated. Figure 10 illustrates schematically how the attraction curve V_A (negative sign) and the repulsion curve V_R (positive sign) are superimposed to give the total interaction curve $V_T = V_A + V_R$. With decreasing particle distance, V_T increases from a shallow minimum (secondary minimum) at a great distance to a maximum and then falls off sharply. When the particles come into direct contact, Born repulsion V_B prevents further approach. Superimposition of V_B and V_T creates the primary minimum.

Because the repulsion V_R varies with the salt concentration, V_T responds sensitively to salt addition. Calculated curves are shown in Figure 11 for latex particles with surface potentials

Figure 11. V_{T}, V_{R}, and V_{A} for latex dispersions at different concentrations of electrolyte ($\nu^+ = \nu^- = 1$) and surface potentials z

d) V_{A}

of $z = 1$ and $z = 2$. As long as a maximum V_{m} separates the secondary and primary minima, the colloidal dispersion is stable. When V_{m} is reduced below ca. 10 kT, the particles aggregate and the dispersion becomes unstable. The salt concentration that initiates this process is the critical coagulation concentration c_{K}.

If coagulation really occurred at the primary minimum, it would be impossible to repeptize the colloid by removing the salt. However, the particles rarely come into direct contact as required for coagulation at the primary minimum. Instead, two or more water layers remain between the particles, so that the "distance of closest approach" is larger and the coagulated particles do not assume the high negative interaction energies of the primary minimum. Figure 12 shows that repeptization is then possible [97], [104].

Figure 12. Energy diagram leading to coagulation (A) and to repeptization (B) [97]

The above formulas refer to spherical particles. For platelike particles the energy of repulsion can be calculated from the following expression

$$V_{\mathrm{R}} = 32\varepsilon\varepsilon_0 \left(RT/(vF)\right)^2 \varkappa\gamma^2 e^{-2\varkappa d} \ \mathrm{J/m^2} \tag{10}$$

The energy of van der Waals attraction is obtained from

$$V_{\mathrm{A}} = -\frac{A}{48\pi}\left[\frac{1}{d^2} + \frac{1}{(d+\Delta)^2} - \frac{2}{(d+\Delta/2)^2}\right] \tag{11}$$

(d, Δ see Fig. 7) [57], [96–99]. The calculation procedure for clay minerals is described in detail by VAN OLPHEN [62]. See also [105–108].

Stability Ratio. Whether coarsening of colloidal dispersions by coagulation occurs rapidly, slowly, or hardly at all depends on the forces between the colloidal particles. In the absence of repulsion forces, the frequency of Brownian encounters determines the rate of coagulation, which is the maximum rate possible (rapid coagulation). Repulsion forces reduce the rate. The maximum V_{m} of the interaction curve (Fig. 10) acts as an activation energy that decreases the ratio of coagulation [97]. The stability ratio (stability factor) W is defined as the ratio between the rate constant (k_0) in the absence of repulsion forces and in their presence (k):

$$W = k_0/k \tag{12}$$

When repulsion forces are absent, $k = k_0$ and $W = 1$; then rapid coagulation occurs. Increasing repulsion decreases the frequency of particle collisions (decreasing k), and W increases. For the influence of the hydrodynamic effect, see [8, Chap. 2], [109], [110]. Colloidal dispersions are considered stable when $W \geq 10^5$. This corresponds to a maximum of $V_{\mathrm{m}} \gtrsim 15\,\varkappa\mathrm{T}$ [96, p. 167]. The dependence of W on the energy of interaction of two spherical particles (in water, 25 °C) is given by [111]:

$$\mathrm{d}\log W/\mathrm{d}\log c = -2.15 \times 10^7 a\gamma^2/v^2 \tag{13}$$

(a: particle radius in cm). Equation 13 is very useful because the effective surface potential ψ_0 or ψ_δ (see Section 6) can be derived easily without knowledge of the van der Waals interaction parameter (Hamaker constant). The dependence of W on the salt concentration can be measured by a simple photometric procedure [111]. When salt is added to a colloidal dispersion, the optical density ($D = \log I_0/I$) increases, as shown schematically in Figure 13. The increase of D with time at the very early states of coagulation (initial linear section of the curves in Figure 13 A) is related to W:

$$\log\left(\mathrm{d}t/\mathrm{d}D\right)_{\mathrm{c}} = \log W - K \tag{14}$$

(K = constant). The values of $\log W$ as a function of $\log c$ are obtained when $\log(\mathrm{d}t/\mathrm{d}D)$ is plotted against $\log c$ (Fig. 13 B, C). This method is widely used for measuring the stability ratio of colloidal dispersions [8, Chap. 11].

Critical Coagulation Concentration. The critical coagulation concentration c_{K} is of fundamental importance in colloid chemistry. It can be obtained directly from a series of V_{T} curves constructed for different salt concentrations. A useful approximation for spherical particles is [96], [100]:

$$c_{\mathrm{K}} = 49.63\,(4\pi\varepsilon\varepsilon_0)^3\,(RT)^5\,\gamma^4/\left(F^6 A^2 v^6\right) \ \mathrm{mol/L} \tag{15a}$$

A = Hamaker constant (in J); at 25 °C, $\varepsilon = 78.5$:

$$c_{\mathrm{K}} = 3.837 \times 10^{-39}\gamma^4/\left(A^2 v^6\right) \ \mathrm{mol/L} \tag{15b}$$

Corrections that may be introduced are discussed in [100]. For platelike particles, the expression is

$$c_{\mathrm{K}} = 8.308 \times 10^{-39}\gamma^4/\left(A^2 v^6\right) \ \mathrm{mol/L} \tag{15c}$$

As discussed before (see page 5) , c_{K} is highly dependent on the valency v (Schulze – Hardy

Figure 13. Experimental determination of the stability ratio W (D optical density)
A) Optical density as a function of time at different salt concentrations; B) and C) log (dt/dD) (from A) and log W (from B) as a function of salt concentration

rule) [8, Chap. 3]. Equation 15 a – c may give the impression that c_K varies with v^{-6}. This is true for high surface potentials ($\gamma \approx 1$), but does not hold at lower surface potentials because v is also included in γ. The quantity c_K then changes with v^{-5}, v^{-3}, or v^{-2} at potentials of 100, 50, and 25 mV, respectively [8, Chap. 3]. Critical coagulation concentrations are generally measured by two methods [8, Chap. 11]. The test-tube method is simple but sensitive. Increasing amounts of salt are added to a certain amount of the colloidal dispersion in a series of test tubes. The tubes are shaken and then allowed to stand for a certain time, usually 24 h. By visual inspection it is determined which dispersions are stable and which are coagulated. The particle concentration must be kept low so that formation of voluminous networks is avoided, concentrations below 1 wt % are generally required.

When the stability factor is determined as described in page 16 and Figure 13, the critical concentration is obtained immediately as the lowest salt concentration at which log W becomes zero or has a minimum. The stability of colloidal dispersions should be studied by both methods because the experiments are based on different time scales. The test-tube investigations reveal the changes that occur over several hours, whereas the photometric turbidity measurements record the initial stages of coagulation. Thus, different critical concentrations are determined in complex systems by the two methods. The differences can be helpful in understanding different coagulation processes. The test-tube method should not be considered obsolete because of the lack of electronic equipment. It is particularly recommended for testing industrial products because it responds sensitively to many experimental parameters and stability changes can be detected over long time periods by visual inspection. When deviations from "ideal" behavior occur, the test-tube tests provide information that may not be noticed by other methods.

Steric Stabilization. The stabilizing action of polymers is significant in many aqueous and nonaqueous systems. The principles of steric stabilization are well understood [8, Chap. 4], [98], [112]. If large molecules or polymers are absorbed on or bound to the particle surface (Fig. 14), a repulsion between the particles is created. When two particles with their envelopes of organic chains approach, the chains in the gap between the particles lose conformational entropy and resist a further approach (volume restriction effect or entropic stabilization, Fig. 14 A). In any case, there is also a local increase in concentration of organic material between the particles (region of the dotted line, Fig. 14 B) and an osmotic effect is produced that exerts a repulsive force between the particles (for terminology see [112]).

The interaction energy due to steric stabilization can be easily calculated by pragmatic formulae [113]. However, it is difficult to find the correct input data, for instance, the segment density distribution of the macromolecules or the contour length of the macromolecular envelope.

In several systems, particularly biological systems, a combination of electrostatic

Figure 14. Steric stabilization
A) Entropic (volume restriction); B) Osmotic; C), D) Electrosteric

and steric stabilization occurs when particles carry surface charges or when the adherent macromolecules are polycations or polyanions (Fig. 14 C, D).

Steric stabilization has ben used by people since ancient times (egyptian "instant" ink, paints, and peptizing agents for clays). Its practical application has been exploited continuously. Industrial applications now comprise polymer dispersions, including latices, emulsions of all types, paints, inks, oils, lubricants, laundry products, and many others.

Typical requirements for steric stabilization are as follows:

1) Steric stabilization requires threshold concentrations of polymers. At low concentrations, sensibilization occurs (see page 27).
2) The amounts of absorbed polymer required for stabilization decrease with the molecular mass of the polymer.
3) The macromolecules should be firmly bound on the surface.
4) The interaction between the macromolecules and the solvent molecules is very important, and the polymer – solvent interaction parameters play a decisive role. Stabilization increases with the quality of the solvent. In a good solvent, interpenetration of the chains is disfavored, promoting stabilization. Conversely, interpenetration is thermodynamically favored in a worse-than-θ solvent, and the dispersion is destabilized. Figure 15 illustrates how sensitively stability responds to the polymer – solvent interaction parameter α.
5) Under θ conditions the system becomes unstable within a narrow temperature range.
6) Change of temperature can favor or disfavor steric stabilization (cf. Table 3).
7) In most cases, destabilization can only be obtained by changing the temperature or the quality of the solvent (changing χ or α) so that θ or worse-than-θ states are established.
8) Destabilization is generally reversible; changing the temperature or the quality of the solvent leads to redispersion and stabilization.

Steric stabilization is widely exploited in industrial processes [115] because of the following advantages:

1) Sterically stabilized dispersions are relatively insensitive to electrolytes.
2) Flocculation (destabilization) is generally reversible; simple dilution with an appropriate solvent is often sufficient to induce the particles to redisperse spontaneously. The particles also redisperse after drying.
3) Steric stabilization at high concentration of solid materials does not produce a comparable increase in viscosity, as occurs in electrostatic stabilization. In the latter case, gels of considerable strength are often formed.
4) Whereas electrostatic stabilization is less effective in nonaqueous dispersion media, steric stabilization can be as effective in aqueous as in non-aqueous media. Steric sta-

bilization is therefore the preferred method of stabilization in organic solvents.

Figure 15. Steric interactions as a function of the solvent parameter α [114]. δ_0 is the normalized distance $H/(r^2)^{1/2}$ where $(r^2)^{1/2}$ is the root-mean-square end-to-end length of the polymer coil in solution.

Steric stabilizers for industrial products are found empirically. Amphipatic block or graft copolymers are widely used as steric stabilizers. They are made up of monomer units that anchor the polymer to the particle and other units that provide stabilization. The anchor unit is one that would not be soluble in the dispersion medium and that has affinity for the particle surface. The stabilizing unit is one that would be soluble in the medium and that imparts mutual repulsion to the dispersed particles. For example, aqueous dispersions can be stabilized by styrene/ethylene oxide copolymers in which the styrene units act as the anchor and the ethylene oxide units provide stabilization. Conversely, a non-aqueous dispersion is stabilized by styrene/acrylonitrile copolymers in which the acrylonitrile units provide the anchor and the styrene units provide stabilization.

An important technique is the grafting of macromolecules to the particle surface by covalent bonds [116–118].

Depletion Effects. Dissolved, nonadsorbable macromolecules can destabilize colloidal dispersions by depletion effects [8, Chap. 4], [119], [120]. The surface of the dispersed particles is surrounded by a depletion zone (thickness Δ) in which the polymer concentration is smaller than in the bulk. The reason is that the reduced conformational entropy of nonadsorbable macromolecules at the surface is not compensated by the adsorption enthalpy. When the particle distance H becomes smaller than $2\,\Delta$ (Fig. 16), the macromolecules are displaced from between the particles. Solvent molecules also leave the interparticle space, so that H decreases, ΔG becomes more negative, and the colloidal dispersion is destabilized by phase separation or flocculation, although the solvent is a better-than-θ solvent for the dissolved macromolecules [121], [122]. The theory claims that in certain cases restabilization can occur at very high polymer concentrations [113], [119], [122]. The typical form of the potential curve is shown in Figure 16. The depletion interaction energy can be calculated by pragmatic formulae [113], [123], [124].

Figure 16. Depletion interaction. The macromolecules leave the space between two approaching particles when the distance H is smaller than $2\,\Delta$; the particle – particle interaction becomes attractive. ϕ_2 is the polymer concentration between the particles, Δ is the thickness of the depletion zone [113]; from [8]
The curve shows the depletion potential V_{dep} as a function of H.

Many systems, particularly practical dispersions like latex dispersions contain particles surrounded by macromolecules and dissolved poly-

mers, and both steric stabilization and depletion effects have to be considered. Also, electrostatic stabilization can be relevant. Stability diagrams are calculated from the corresponding equations by assuming the different interactions (electrostatic, van der Waals, steric, depletion) to be additive, which is not always the case. For examples of such calculations, see [125–128].

6. Factors Controlling Colloid Stability

Surface Charge. The imperative requirement for electrostatic stabilization is the presence of electric charges on the particle surface. There are several mechanisms for producing these charges:

1) In many silicates, including clay minerals and zeolites, isomorphous substitutions (most common is Al^{3+} for Si^{4+}) and cation vacancies produce negative surface charges. The surface charge density σ_0 is invariantly determined by the substitutions and vacancies and does not change with experimental conditions (concentration, pH, etc.).
2) Oxides like SiO_2, Al_2O_3, Fe_2O_3, and TiO_2 carry OH groups on the surface that can dissociate or adsorb protons. Silanol groups, for instance, are protonated at very low pH (< 2) and the surface is positively charged. With increasing pH, the surface charge density decreases and becomes increasingly negative above the point of zero charge (pzc) because of the dissociation of silanol groups (Fig. 17). Analogously, SH^- groups impart surface charges to colloidal sulfides. In both cases the surface charge density is not constant, but changes with pH.
3) Sparingly soluble salts such as silver iodide may have an excess of Ag^+ or I^- ions on the surface depending on the Ag^+ or I^- concentrations in the solution. (The concentrations of Ag^+ and I^- ions in solution are related to each other by the solubility product L: $p\,Ag + p\,I = p\,L = 16$). The silver and iodide ions act as potential-determining ions; thus AgI particles are positively charged at Ag^+ concentrations above the pzc (at $p\,Ag^0 = 6$) and are negatively charged at Ag^+ concentrations below $p\,Ag^0 = 6$.
4) Metal colloids are usually charged by absorption of ions, for instance Cl^- and citrate anions on Au and Pt particles ([8], [17]).
5) Commonly, latex particles carry $-SO_4H$, $-SO_3H$ or $-COOH$ groups on the surface. Sulfate and sulfonate groups dissociate the proton at low pH so that in pH ranges of practical applications the surface charge density is invariant with pH. The weakly acidic $-COOH$ groups dissociate at $pH \leq 4$, so that the surface charge increases considerably at $pH \leq 4$.

a) Precipitated silica [129]; b) TiO_2 [130]; c) Hematite [130]

Consequences of Surface Charge Changes. Above several systems are described in which the surface charge density changes with experimental conditions (pH and concentration of potential-determining ions). When parameters are chosen so that the particle charge disappears (point of zero charge), the dispersion becomes highly unstable and coagulates. The stability factor has a sharp minimum (cf. Fig. 32 A) because the surface is recharged by crossing the pzc, and the system restabilizes. Thus, small pH changes near the pzc can have dramatic effects on the stability of colloidal dispersions.

Figure 18. Stability ratio of PTFE latex as a function of pH in NaCl solutions [131]

The effect of pH changes on the stability of PTFE latex dispersions is shown in Figure 18. Because of the increased surface charge density the dispersion tolerates a tenfold higher salt concentration at pH = 5.8 than at pH < 2.5 before becoming destabilized.

Specific Adsorption. The simplest model, developed by Stern (1924), assumes that the number of ions adsorbed on a particle surface is restricted by their size (including their hydration or solvation shell) and that specific interactions between the counterions and the surface may occur [8, Chap. 9], [82], [132]. The aqueous part of the ionic layer is divided into a Stern layer and a diffuse or Gouy – Chapman layer. The "Stern surface" is drawn through the centers of the ions that are assumed to be adsorbed on the particle surface; the potential decreases linearly from ψ_0 at the particle surface to ψ_δ at the Stern surface and then exponentially in the diffuse layer (Fig. 19).

The thickness δ of the Stern layer is usually assumed to be about 0.4 nm (two water layers). Some generalizations can be made:

1) The existence of the Stern layer does not invalidate the expressions for the diffuse part of the double layer. The double layer interactions are determined by the Stern potential ψ_δ. Thus ψ_δ has to be used instead of ψ_0 in the Equations 7, 8, 10.
2) As adsorption in the Stern layer increases, ψ_δ is reduced and the interparticle repulsion is diminished. In the limiting case where the counterions are strongly absorbed, $\psi \approx 0$, and the system becomes unstable.
3) As the electrolyte concentration increases, adsorption in the Stern layer increases and reduces ψ_δ, even if specific interactions are absent.
4) ψ_δ varies only slightly with the energy of specific interactions until this energy is relatively large.
5) A study shows that, even in simple systems like AgI with potassium and barium counterions, Stern layer adsorption must be taken into consideration [133]. The specific adsorption energies are of the order of $4-6\,kT$ for potassium and $5-8\,kT$ for barium ions.

Several other models were developed to describe the behavior of the ions at the surface [8, Chap. 9], [82]. The triple-layer model is often used. On the basis of such models, equilibrium constants of the reactions of the surface groups were evaluated from potentiometric titrations. However, these values should be considered cautiously [132], [134].

Figure 19. Stern layer and diffuse ionic layer around colloidal particles

Solvent Effects. Solvent parameters are of decisive importance for sterically stabilized systems (see page 17). This section describes the changes that occur when, under conditions of electrostatic stabilization, water is replaced by or mixed with polar organic solvents. A dependence of the critical coagulation concentration on ε is generally observed but does not follow the relation $c_K \sim \varepsilon^3$ as required by Equation (15) [135–137].

The principal effect of organic solvents (with $\varepsilon < 80$) is to press the counterions into the Stern layer, thus reducing ψ_δ and the stability of the dispersion toward salts [133]. The effect can be quite strong for multivalent counterions. In an extreme case, "equivalent coagulation" occurs [136]. When the bi- or trivalent counterions are added to the dispersion, the surface charges are neutralized, the particles become uncharged and the dispersion coagulates. The critical counterion concentration is then distinctly lower than that for coagulation by compression of the double layer and decreases with the concentration of the particles.

In some cases, high content of organic solvent suppresses the dissociation of the surface groups and the surface remains almost uncharged. Very low concentrations of monovalent counterions then coagulate the dispersion (≈ 0.001 mol/L for Ag and α-FeO(OH) particles in acetone [136]).

The effect of organic solvents is therefore not sufficiently described by changes in the dielectric constant. For instance, isopropanol and acetone affect the colloid stability more strongly than methanol and ethanol although their dielectric constants are not much lower. The effect of the organic solvent on the structure of the continuous phase, on the dissociation of surface groups, and on the solvation of the ions and their distribution between the Stern and the diffuse layer are important to the stability of dispersions in organic solvents or their mixtures with water.

Stabilization by charges can also occur in nonpolar solvents [8, Chap. 2]. As the concentration of charges is extremely low in such solvents, $\varkappa$ is very small (Eqs. 6 a – c) and the ionic layer very large, that is, the potential decreases very slowly with increasing distance from the surface. Therefore, high zeta potentials are often observed in such dispersions.

Effect of pH. Changes in pH can considerably influence the stability of colloidal dispersions when the surface charge density is pH-dependent. This is particularly true for oxides, sulfides, and latices with surface COOH groups (Fig. 18). The behavior of TiO_2 dispersions is shown as a further example (Fig. 21). The counterions are anions at pH below the zero point of charge, and cations at pH > 3. The above-mentioned influence of the ions of homologous series (see page 5) is clearly evident.

Figure 20. Dependence of the critical coagulation concentration c_K on pH for silica sol (Ludox sol, 0.2 g SiO_2 /100 mL) [138]

Figure 21. Specific ion effects for the coagulation of rutile (TiO_2) dispersions: the critical coagulation concentration c_K as a function of pH. At pH < 3 anions are the counterions; at pH > 3 cations are the counterions [139]; from [8]

The influence of pH on the stability of silica sols is striking (Fig. 20). The decreasing c_K for NaCl and $CaCl_2$ in the alkaline range, however, is opposite the behavior expected from Figure 17. This behavior is important in practical systems but is not understood completely. Deformation and decomposition of a hydration layer around the SiO_2 particles by the increased negative charge density is the most plausible explanation. Repulsive and attractive hydration forces are discussed in [8], [140]. The increase of the c_K values of the TiO_2 dispersions in the presence of alkali metal ions (Fig. 21) is not as strong as would be expected from Fig. 17, and this may be for similar reasons.

The flow behavior (viscosity, yield value) of dispersed oxides is also pH-dependent. Both properties often show maximum values at the point of zero charge (Fig. 22) [141] because the disappearance of the electrostatic repulsion promotes aggregation of the particles. This behavior is very important for practical applications. Sometimes, undesirable thickening or thinning of dispersions can be reduced by changing the pH. The viscosity and yield value at a given pH can also be decreased by adsorption of appropriate anions. Adsorption of polyacrylate, for instance, shifts the maximum yield value of ZrO_2

Figure 22. Yield value τ_0 of some dispersions as a function of pH at 25 °C
a) Alumina (Type C, Degussa, solid content 10 wt %). b) Titania (P25, Degussa, 7.5 wt %). c) Silica (Aerosil 200, Degussa, 8 wt %) [141]; from [8] pH $\triangleq$ pH in Fig.

dispersions to lower pH values (Fig. 23). Similar changes were observed with many other anions (phosphate, citrate, benzenecarboxylic acids, etc.) [142].

Multivalent Ions. Colloidal systems respond very sensitively to multivalent cations (Schulze – Hardy rule). Aluminum and iron ions are thus the preferable counterions for coagulating colloidal systems. Multivalent cations, in particular tri- and quadrivalent ions, can influence the colloid stability in a way different from the behavior expected from the Schulze – Hardy rule for $\nu = 3$ or 4:

1) First, aqueous solutions of these cations are acidic and change the pH of the system, so that pH effects as described can occur, in particular when the pH is near the pzc.
2) Multivalent hydrated cations condense to form larger complexes with a high charge, which decreases the stability. The stepwise decreasing critical concentration of aluminum sulfate and nitrate at pH 4 – 5 in AgI dispersions is explained on this basis [138].
3) The specific adsorption of counterions in the Stern layer is more pronounced for multivalent ions than for monovalent ones. In extreme cases, the surface charges are neutralized by the multivalent counterions so that the system reacts very sensitively to such ions ("equivalent coagulation" see page 23).
4) An excess of multivalent counterions on the surface recharges the surface:

Figure 23. Yield value τ_0 of ZrO_2 dispersions in the presence of polyacrylic acid ($M = 2000$) as a function of pH. m = amount of polymer (g/100 g ZrO_2) [142]; from [8]

Thus when increasing amounts of multivalent ions are added to a dispersion, the system can pass from stabilization to destabilization (charge neutralization) and again to stabilization (recharging). Recharging and restabilization of SiO_2 sols with increasing concentrations of La^{3+} are perceptible in Figure 20. One might expect that recharging by aluminum salts is optimal at low pH when Al^{3+} ions are present. Figure 24, however, shows that recharging occurs at higher pH (pH 4 – 5, depending on the aluminum salt concentration). It is assumed that recharging is brought about by the adsorption of hydrolyzed metal ions [138]. At higher pH precipitation of the metal hydroxide is initiated. Surface precipitation usually occurs under conditions different from precipitation in homogeneous solution. As a consequence of surface reactions, the zeta potential can change in a complex manner (Fig. 25) [143].

Figure 24. Zeta potential of PVC latex (0.003 wt %) as a function of pH in the absence and presence of $Al(NO_3)_3$ (Arrows indicate the isoelectric points. All systems contained 1×10^{-3} mol/L $NaNO_3$.) [138]

Multivalent anions (e.g., SO_4^{2-}, PO_4^{3-}, oxalate) are often strongly adsorbed by oxides or incorporated into the surface instead of oxygen or hydroxyl ions with considerable changes of the pzc.

Figure 25. Dependence of zeta potential on pH in the presence of hydrolyzable multivalent metal cations of concentration $c_1 < c_2 < c_3$
A) Oxide in absence of metal cations; B) Colloidal metal hydroxide
The dispersion becomes unstable at zeta potentials lying between the dotted lines [143]; from [8]

Complexing Agents. Complexing of countercations by anions often causes antagonistic effects. Thus, fluoride and sulfate ions (at pH < 4) can decrease the coagulation power of aluminum ions (increasing c_K) [138]. An opposite effect is observed when the counterions are adsorbed as complexes. Addition of small amounts of complexing agents can then decrease the c_K by orders of magnitude [144].

Surface Active Agents. Surfactants with counterionic charge are strongly adsorbed at the particle surface. Charge neutralization ($\psi_\delta = 0$) with rapid destabilization of the colloidal system requires specific concentrations because recharching and restabilization can take place by adsorption of an excess of surfactant ions together with their counterions (Fig. 26). This process is promoted by the tendency of the long-chain ions to aggregate to monomolecular or bimolecular films. In the case of low surface charge densities, the surfactants form small surface aggregates [145]. Adsorption of surfactant counterions on oxidic surfaces is often accompanied by charge regulation. For example, after compensation of positive surface charges by surfactant anions, adsorption of further anionic surfactants causes the adsorption of protons by surface groups, so that the density of the positive surface charges increases and the zero point of charge increases with increasing pH [167].

The charge reversal by adsorption of alkylammonium ions on quartz is illustrated in Figure 27. Longer alkyl chains shift the pzc to lower surfactant concentrations by orders of magnitude. The effect of a particular surfactant depends on pH, which determines whether the surface of the oxide is positively or negatively charged. Thus, dodecyl sulfate causes charge reversal and restabilization of Al_2O_3 sols only at a pH below the pzc of pure Al_2O_3 sols (pH < 8) when the surface is positively charged. The importance of the way in which oxides are produced industrially can be exemplified by TiO_2. TiO_2 prepared in the absence of sulfate or phosphate ions adsorbs tetradecylpyridinium ions only at pH > 5. In the presence of sulfate ions, which are strongly held on the surface, the surfactant is adsorbed throughout the whole pH range, with a minimum at pH ≈ 6, and a complex surfactant layer is formed [146], [147].

Figure 26. Adsorption of surfactant counterions at hydrophilic surfaces
A) charge neutralization; B), C) Recharging by an excess of surfactant counterions at high (B) and low (C) surface charge density; D) Adsorption of surfactant cations on the positively charged TiO_2 surface in the presence of sulfate ions [146], [147], [145].

Figure 27. Influence of salts and surfactants on the zeta potential
A) Ammonium acetate (- - -) and alkylammonium acetates (–) of various chain lengths on quartz (n of alkylammonium ions $C_nH_{2n+1}NH_3^+$ as indicated) [148];
B) Sodium chloride (- - -) and dodecylsulfate (–) on corundum at different pH [148]

Polymers. Polymers influence the stability of colloid dispersions in different ways (Fig. 28) [8, Chap. 4]. Stabilization or destabilization of colloidally dispersed systems are used in many technical applications. Usually, low concentrations of macromolecules decrease the stability of colloidal dispersions (sensibilization) whereas higher concentrations stabilize the colloidal state, in many cases in extreme ways. The stability factor W as a function of polymer concentration proceeds through a minimum that indicates the highest degree of sensibilization (Fig. 29). Besides the stabilization effect, the adsorption of polymers can change the behavior of the systems to salts. PVA-stabilized silica responds sensitively to Na_2SO_4 and KCl but is not coagulated by $CaCl_2$ [149].

Sensibilization at low polymer concentration is brought about by macromolecules bridging between the particles or by charge neutralization when charged polymer ions displace the counterions from the surface (Fig. 30 A, B). Charge neutralization can also occur patchwise (Fig. 30 C). The charges are not compensated site by site, but the total charge of the particle becomes zero as a consequence of negative and positive domains. To bridge the particles, the macromolecular charge must not be opposite to the surface charge; it is only required that the macromolecule can attach itself at some sites at the surface so that larger parts of it remain free to form bridges between different particles. Practical applications prefer the sensibilization by particle bridging because charge neutralization requires a careful adjustment of parameters to prevent charge reversal and restabilization. Polyanions are therefore widely used as flocculating agents for clay materials [14], [150].

Formation of flocs by polymer addition can retard the adsorption equilibrium because solvent remains trapped within the flocs. The amounts adsorbed then depend on the manner of mixing, stirring, shaking, etc., and reproducibility of the measurement can be poor [151].

Stabilization at higher polymer concentrations is caused by steric stabilization. This process is often the only process that allows stabilization in nonaqueous solvents.

With highly anisometric particles the sensibilization region can be preceded by a stabilization region at very low polymer concentrations so that a sequence stabilization $\rightarrow$ sensibilization $\rightarrow$ stabilization is observed with increasing polymer concentration (polyacrylamide onto kaolinite [152]).

Mechanical Effects. In laboratory experiments colloid stability usually is measured under perikinetic conditions, that is, the particles collide owing to the Brownian motion of the solvent molecules. In practical applications, the dispersions are shaken, stirred, or transferred by pumping. The mechanical forces intensify the particle flux, which depends on the third power of the collision diameter of the particles [76]. Orthokinetic aggregation is therefore more important for larger than for smaller particles. Thus, orthokinetic destabilization can be very effective for emulsions.

Under orthokinetic conditions, hydrodynamic forces are in interplay with the forces bet-

Figure 28. Stabilization and destabilization of colloidal dispersions by macromolecules [8]

Table 3. Effect of changing the stabilizing species on emulsion stability [158]

Type of emulsion	Stabilizing moiety ∗	Anchor polymer ∗	Dispersed phase	Dispersion medium	Flocculation on	Type of stabilization	Critical flocc. temp., K	θ-Temp., K

ween the colloidal particles [8, Chap. 3], [153–155]. It is difficult to predict the behavior of colloidal dispersions under shear. The stability and destability regions depend on the rate of shear, the particle size and size distribution, and the interparticle forces in a complicated way. Even small changes in parameters can strongly influence stability at low and high shear rates. A calculated diagram is shown in Figure 31. The dispersion is unstable ($\log W < 5$) at low but also at high shear rates. At low shear rates the dispersion coagulates in the secondary minimum (see Fig. 10), at high shear rates in the primary minimum [156]. In many technical processes coagulation occurs under turbulent flow but not much is known about this process [154].

Stability against shearing plays an important role in industrial processes such as coating and production of thin-layer ceramic films. Further, dispersions should not destabilize during shaking (transport), stirring, or pumping. Sometimes a dispersion is stable for years but coagulates in a short time on shearing. Because of the complicated dependence on the particle size, two latex dispersions with different particle sizes can be stable against shearing but the mixture can be unstable. To avoid undesirable shear coagulation the stabilization mechanisms, particle shape, size and size distribution and the chemical parameters (pH, salt content, presence of organic compounds) must be critically evaluated. Dispersions of oxides often coagulate under shear when pH is near the zero point of charge (see page 23).

Adsorbed stabilizer ions or macromolecules can be desorbed by shearing. It is known that emulgator molecules can be removed from the surface of latex particles by centrifugation [8, Chap. 6] which reduces the stability of the dispersions.

Shearing can change the structure of adsorbed macromolecules, and this can also reduce stability. Otsubo and Watanabe [157] observed, at low shear rates, a stepwise in-

crease of the viscosity of silica particles stabilized by adsorbed polyacrylamide. Depending on the molecular mass, the solvency of the solvent, the solid mass content, and the particle size, macromolecular bridges formed between colliding particles during shearing increased the viscosity.

Macromolecules which are desorbed by shearing can cause flocculation by depletion effects.

Temperature Effects. Temperature effects are most pronounced for sterically stabilized systems. It depends on the type of stabilization – mainly enthalpic or mainly entropic – whether a dispersion flocculates on cooling or heating. When enthalpy effects dominate, the system flocculates on heating. If enthropic effects are important, the sol flocculates on cooling. Examples of water-in-oil and oil-in-water emulsions are given in Table 3 [158]. Every sterically stabilized system flocculates under θ conditions and at the θ temperature (see page 17) [8, Chap. 4], [112].

Figure 29. Variation of the stability ratio with the concentration of polymers

Electrically stabilized dispersions are not very sensitive to temperature provided structural changes do not occur. When such changes take place, the dispersion becomes sensitive to temperature and can destabilize within a narrow temperature range (thermosensitive latex dispersions). Temperature sensitivity can also be attained by choosing as counterions complex ions that decompose at higher temperature, for instance $[SiF_6]^{2-}$ counterions. Thermosensitive poly(*N*-isopropyl acrylamide) latices (NIPAM latices) were studied in detail [159], [160]. The van der Waals attraction increases when the particles shrink above 30 °C and reduce the stability of the dispersion [161].

7. Heterocoagulation

Colloidally dispersed oxides can be separated by choosing appropriate pH values. For example, in quartz-rutile dispersions, both types of particles are negatively charged at pH $\approx$ 9.5 but can be separated by making the dispersion 0.015 – 0.050 mol/L in NaCl [162].

If the different particles carry opposite surface charges, heterocoagulation occurs in specific pH ranges. This is illustrated for $TiO_2 - Al_2O_3$ dispersions in Figure 32 A. At any pH between the pzc of TiO_2 and Al_2O_3, the TiO_2 particles are negatively charged whereas the Al_2O_3 particles are positive, and heterocoagulation takes place. Thus, TiO_2 can be selectively separated from mixed dispersions only at a pH below the pzc of TiO_2 and, correspondingly, Al_2O_3 above the pzc of Al_2O_3. Experimental observations (Fig. 32 B, [163]) confirm the expected behavior, but only if coagulation is initiated immediately after the TiO_2 and Al_2O_3 dispersions are mixed. If the mixed dispersion is allowed to stand before coagulation, it behaves like a pure Al_2O_3 dispersion. Soluble aluminum species are adsorbed by the TiO_2 particles, so that the particles become coated by Al_2O_3 and behave like Al_2O_3 particles. This example demonstrates that the stability of a colloidal dispersion of two or more different particles can be considerably affected by the adsorption of soluble species.

When aluminum nitrate is added to a PVC latex, distinct regions of stabilization and destabilization are observed (Fig. 33, [164], [165]). Since the anionic PVC latex has an isoelectric point (iep) $\approx$ 3, domains a and g represent stable negative sols of PVC (a) and PVC + Al_2O_3 (g). In domain b the latex particles are coagulated by Al^{3+} ions. In region f, the latex particles absorb hydrolyzed aluminum ions, become positively charged (recharging, cf. Fig. 24), and form a stable dispersion. In region c, PVC and Al_2O_3 coprecipitate, probably because recharging of the PVC latex ceases (cf. [143]) so that heterocoagulation occurs between negative PVC and positive Al_2O_3 particles.

Figure 30. Destabilization of colloidal dispersions by macromolecules
A) Flocculation by charge compensation; B) Bridging flocculation; C) Flocculation by charge pattern interactions (mosaic model). The domains with adsorbed polycations receive a positive excess charge, which is compensated by the negative charge of the uncovered surface patches

Figure 31. Influence of shearing on colloid stability. Stability factor W versus rate of shear for particles of 1 and 10 mm diameter. Stern potential 25 mV, $\varkappa = 10^8\ \mathrm{m}^{-1}$, Hamaker constant $A = 10^{-20}$ J [156]; from [8]

Heterocoagulation has also been studied with amphoteric latices [166]. By variation of the ratio of $-COOH$ and $-NH_2$ groups, latices with a different pzc can be prepared. The stability ratio of mixtures of latices with a different pzc follows the theoretical prediction. The behavior of negative latices in the presence of negative amphoteric latices toward salts exhibits some interesting features. The negative latex appears to be more easily coagulated in the presence of a negative amphoteric sol.

In practical applications heterocoagulation can occur during mixing of two different types of dispersions. To obtain a stable mixture, one kind of particle must be recharged by addition of suitable compounds like trivalent metal ions, complexed metal ions, or ionic surfactants.

A novel application of heterocoagulates is the stabilization of oil-in-water emulsions by clay minerals and layered double hydroxides without any surfactant emulsifier [47], [48], [94].

Figure 32. Coagulation of $Al_2O_3-TiO_2$ dispersions
A) Variation of surface potential and stability ratio with pH, schematically (–pure sols, – – – $Al_2O_3-TiO_2$ sol); B) Experimental results in 10^{-4} mol/L KNO_3 at 15 s and 24 h after mixing [163]

Figure 33. Stability diagram of a PVC latex (0.005 g/100 ml) in presence of $Al(NO)_3$; (- - -) variation of point of zero charge; (· · · ·) precipitation boundary of aluminum hydroxide; a) – g) see text [165]

1. Definition

Structure as a Basis for Definition. The word *composite* is used in the technical sense to describe a product that arises from the incorporation of some basic structural material into a second substance, the *matrix*. That which is incorporated can be in the form of particles, whiskers, fibers, lamellae, or a mesh. Its task is to impart its own advantageous mechanical characteristics to the matrix material. Composites can be produced either by thermomechanical mixing of individual components or by means of chemical reactions that lead to phase separations within homogeneous starting mixtures (cf. page 2).

To obtain a composite with desirable mechanical properties, it is necessary that the separation between the incorporated elements be in the range of 0.01 – 1 mm and that the incorporation show directional characteristics. The extent of mutual adhesion and interpenetration of the components must also be favorable.

The key characteristics sought in an incorporated substance, which are in turn conferred on the composite, are above all elastic rigidity, tensile and fatigue strength, and hardness, as well as appropriate electrical and magnetic properties. Glass fiber reinforced resins are typical examples of composites, and these are probably the best known (→ Reinforced Plastics).

Composite materials and glass fiber reinforced plastics, respectively, are known in German as "Verbundwerkstoffe" and "glasfaserverstärkte Kunststoffe," and in French as "matériaux composites" and "matière plastique armée aux fibres de verre."

Modes of Preparation as a Basis for Definition. The most common way to produce composites entails thermomechanical introduction of one or more additive components R_1, R_2, $R_3, \ldots$, into a preexisting matrix. Particularly suitable techniques include winding and infiltration (see the literature sources cited above). Extrusion [7] and thermal injection [8] methods have also been described. The variety of possible forms that composite materials can take and the number of possible component combinations are large. Finishing of the materials presents no major problems; the appropriate technology is both proven and cost effective. Rather, it is the preparation of composites in suitable form that tends to be costly.

An interesting alternative to thermomechanical mixing is the possibility of using a phase-separation process within a homogeneous starting material to create the desired heterogeneity. The following processes lend themselves to this approach: eutectic crystallization from a melt, eutectic decomposition of solid solutions, or phase separation within a supersaturated solid solution [9], [10]. Composites that form to some extent in this way within partially prefabricated construction elements are known as *in situ composites.*

The method is a particularly elegant one, and it affords an opportunity to produce exceedingly fine geometric distribution of the phase components. Moreover, constituents that are difficult to prepare or handle can sometimes be introduced by this method. Nonetheless, the following are disadvantages:

1) The number of multicomponent systems suited to the approach and at the same time capable of yielding desirable properties is extremely limited.
2) The resulting ratio of matrix : included phase is often a fixed property of the system.
3) Reactions of this kind proceed under diffusion control and with a finite number of transport paths to the growing front. Moreover, both of these parameters change during the course of the reaction. To introduce a measure of selectivity on the directional characteristics of the composite, the reaction must be correspondingly controlled, for example, by provision of a steep temperature gradient in the direction of desired growth. Thus, production is slow, highly subject to interference, and limited to geometrically simple forms.

A material prepared in the latter way through controlled solidification of a eutectic mixture is referred to as a *directionally solidified eutectic,* commonly abbreviated DSE.

The method of phase separation is best suited to the manufacture of small items that are subject to rigid demands, where cost plays a minor role (e.g., for turbine blades or microcomponents) [11].

Both approaches are represented schematically in Figure 1.

Figure 1. Symbolic comparison of the two principal approaches to the manufacture of composite materials
A) Thermomechanical mixing; B) In situ preparation by phase separation

Distinction from Other Classes of Materials. The definition provided above is occasionally criticized as being too narrow, where the objections arise from the point of view of the material sciences. Thus, it is argued that it is the nature of the interaction between two or more finely divided materials that determines measurable macroscopic properties of a composite, not the way the mixture is prepared or the purpose it is intended to serve. The very fact that oriented materials resulting from eutectic crystallization are called in situ composites demonstrates that the eutectic mixture itself determines the properties of the composite. This line of reasoning suggests that all eutectic mixtures (not only those that are oriented) should be regarded as composites – including cast iron, Al – 12 % Si alloys,

and soft solder. It is further asserted that no fundamental difference exists between an inclusion comprised of Ti/W carbides in a Co matrix and the product resulting from distribution of Cr and Nb carbides in a ferrite matrix, whereas only the former system (cemented carbides) is normally referred to as a composite. Similar argumentation can lead to the conclusion that paper and even the natural product wood are composite materials.

The term "composite" is not normally used in as broad a sense as this interpretation would suggest. Therefore, it is preferable to employ a more general term such as "multiphase" material (or solid) when one is discussing the general relationship between microstructure and macroscopic properties, and to reserve the word "composite" for cases in which some specific characteristic of an incorporated material is intentionally being exploited. The latter criterion does not apply to most eutectic or precipitation-hardened alloys. It is true that the hardness of a carbide or intermetallic compound that is introduced into a metal matrix does contribute strengthening characteristics, but this is not a property that is exploited as such. In glass fiber reinforced resins, on the other hand, the elastic rigidity of the glass fibers is the desired property. Similarly, the hardness of carbides is the reason these are added in the preparation of hardened alloys, and asbestos fibers are what supply the tensile strength of asbestos cement.

Cast iron represents an interesting borderline case. Gray cast iron with eutectically oriented graphite lamellae is often employed in applications in which the damping properties of the graphite lamellae are advantageous. White cast iron, on the other hand, is preferred for purposes that require hardness, where eutectic carbide is performing the same function as in hardened alloys. Nevertheless, the historical development of both forms of cast iron was unrelated to such considerations, so that it is reasonable to conform to tradition and refrain from designating cast iron as a "composite."

It is also inappropriate to describe as a composite a macroscopic material into which whole structural elements (wires, meshes), themselves homogeneous, have been introduced for the purpose of improving mechanical or other properties (e.g., steel-reinforced concrete and steel-belted tires). The same is true even if the union of materials is conducted in a layered fashion (e.g., plywood) or by coating. Similarly, sheet steel or pipe stock that has been electrolytically nickel plated, galvanized, plated in a rolling mill, or plastic coated is not a composite material.

2. Classification

2.1. Geometric Classification

A reinforcing agent is introduced into a given matrix in the form of particles. These are understood to exist as dispersed entities with planar (usually crystalline) or rounded boundary surfaces. For a particular particle shape, the relationship of particle radius r to the distance between centers of adjacent particles d determines the volume fraction f of the composite material, relative to the volume V:

$$f = V_R / (V_M + V_R) \tag{1}$$

Throughout this section the subscript R is used to refer to the incorporated reinforcing material, wheras the index M signifies the matrix. The maximum volume fraction that can be obtained by closest spherical packing of spherical particles of uniform radius is $f_{max} = 0.680$. Higher values of f can be attained by using particles of varying diameter if these are arranged (e.g., by applying vibration) so that smaller spheres occupy the spaces between larger ones. According to [12], space filling that approaches 95 %, for example, results from the layering of spherical particles of radius ratio of 1 : 7 : 40 : 320 in a volume relationship of 6 : 10 : 25 : 59. Even higher degrees of admission are possible if the spherical shape is abandoned, as shown by the polycrystalline structure of metals and ceramics. Thus, cubes and hexagonal dodecahedra would, in theory, lead to values of 100 %. Other particle shapes (ellipsoids) reduce the potential packing density, but at the same time they open the way to establishing preferential orientation.

Whiskers are monocrystalline fibers that are largely free of defects and are thus subject to elastic deformation even under extreme tension (→ Fibers, 5. Synthetic Inorganic). Such whiskers can be obtained by the chemical vapor deposition (CVD) process, which entails reactive deposition from the gas phase. Whisker

diameter ranges from 0.1 to 1 μm, and is thus an order of magnitude below that of ordinary fibers. Their length reaches 0.1 – 1 mm. Whiskers exhibit very high mechanical strength as a result of their lack of defects. Tensile strengths ca. 10 % as large as the elastic modulus have been measured, a value 5 times that associated with a high-quality polycrystalline fiber and 100 times as large as that for massive polycrystalline material. Unfortunately, the preparation and handling of whiskers is both difficult and costly. Despite 20 years of developmental effort, it has still not proven possible to mass produce them, although well over 100 substances have been prepared as whiskers on a laboratory scale. Expectations were high – probably unrealistically so – in the 1960s for future applications of whiskers, but these have been largely unfulfilled [13]. In principle, whiskers should be ideal components for use in composites, since this application is one that would take full advantage of their remarkable strength while at the same time making available in the form of the matrix a suitable container and protective coating.

Fibers are incorporated into composites in both short and continuous forms, although even the so-called short fibers rarely have length: radius ratios under 20. In most cases the fiber's high rigidity or tensile strength is to be conferred upon the composite material. Thus, a key role is played by the transfer of forces out of the matrix and, therefore, by the microgeometry and wettability of the boundary surfaces. For this reason, the fibrous materials are often either provided with a coating or in some other fashion "activated."

Most fiber-reinforced composites are distinguished by the rigid orientation of their fibers ("unidirectional composites," UDC). This leads to a distinctive directionality with respect to macroscopic (e.g., mechanical) properties of the materials as well – they show high strength in the direction of the fibers, but show poor characteristics in the transverse direction. Weakness of this kind intolerable is in many applications (e.g., in automotive components). One way to compensate for this weakness is through introducing fibers in the form of a mesh (laminates) rather than unidirectional single fibers. Resulting improvements in strength transverse to the principal axis of stress are obtained at a price, however: the effective volume fraction in the direction of primary stress is substantially reduced, as is the corresponding carrying capacity. The same holds true for irregular "fleecy" inclusions.

2.2. Material Classification

Since the volume fraction of fibers in a composite rarely exceeds 0.5, the general appearance of the material is conferred by the matrix. This fact is reflected in the terminology that is employed (e.g., fiber-reinforced resin). Almost all of the known structural material types can play the part of the *matrix.*

High polymers are used as building materials [14], [15]. Most often encountered are unsaturated polyester (UP) and epoxy (EP) resins. Other examples include polyacrylate dental materials containing silicate particles and polypropylene to which glass fibers have been added for use in shatterproof safety glass.

Metals are less commonly used for ordinary temperature composite materials because of their undesirable weight. Exceptions include aluminum and other light-metal alloys strengthened by the incorporation of boron, SiC, or carbon fibers [16], [17]. Al_2O_3 whiskers are, of course, also utilized, although the economics involved are far from ideal. Strengthening through the use of steel threads has also been studied [18].

One important domain of fiber-reinforced metal composites is the area of high-temperature applications. The use of organic matrices is here excluded, although ceramic reinforcing materials represent an alternative. A special case of growing importance is the category of in situ composites (oriented eutectic mixtures, already mentioned above). Examples of the latter include Ni – Co-based materials containing fibrous TaC, or ones based on Fe and reinforced with $(Cr,Mn)_7C_3$.

Cobalt-based alloys containing particulate WC/TiC (so-called hardened alloys) are also employed on a large scale for cutting tools.

A third domain of metal-based composites includes materials for electrical engineering applications, such as contacts [19], [20].

Ceramics containing fibrous materials (Al_2O_3, SiC, and B_4C) have come into use as lightweight bulletproof shields (e.g., helmets,

vests, and helicopter seats), though civilian applications exist as well.

Cement containing asbestos, glass, plastic, or steel threads has numerous uses in the construction industry, especially for poured concrete structures. Also noteworthy is the high impact resistance of concrete reinforced with polypropylene fibers [23–25].

Rubber can also serve as the basis for composites, as in preparations containing magnetic particles ("magnetic rubber").

Materials with proven value as *fibrous reinforcing agents* for composites include the following:

Glass fibers, especially those derived from E-type glass (aluminum – boron – silicate glass) and, for better elastic properties, S-type glass (SiO_2– Al_2O_3– MgO) – these materials are also introduced in fabric or fleece form.

Carbon fibers, prepared by the pyrolysis of cellulose or polyacrylonitrile fibers at high temperature and under inert atmosphere – if the final stage of the thermal treatment is carried out at ca. 2800 °C, the material is converted largely into a graphite possessing exceptional tensile strength [26], [27].

Tungsten-core fibers, including boron, B_4C, and SiC – these are prepared by thermal decomposition of halides on a tungsten core.

Metal fibers can be prepared from the extremely light but toxic beryllium, as well as from steel, niobium, molybdenum, and tungsten. Their advantage is their plastic ductility (albeit restricted within specific limits), but they have the disadvantage of great weight.

Ceramic fibers – these include important natural fibers (asbestos, especially in its chrysotile modification), but synthetic ceramic fibers are also known (though largely on the laboratory scale) [28].

Hybrid composite materials containing two or more additives (e.g., carbon and glass fibers) are increasingly important because they represent a means of creating a balance between the advantages and the disadvantages shown by individual components.

3. Principles of Fiber Reinforcement [1–6]

3.1. High-Strength Fiber Composites

Despite the complications attending their preparation, composite materials represent an interesting alternative to metals whenever there is a demand for great strength with minimal mass. To characterize this property, it is common to employ either the term *specific strength* $R_m/(\varrho \cdot G)$ (ϱ = density in g/m^3, $G = 9.80665$ m/s^2 = gravitational acceleration) or else the *specific modulus of elasticity* (Young's modulus) $E/(\varrho \cdot G)$. Since $\varrho \cdot G$ has the unit N/m^3, whereas R_m and E are in N/m^2, the resulting specific quantity has the unit m. In practice, data are normally reported in km; e.g. $E/(\varrho \cdot G)$ for graphitized carbon fibers is 2000 km. This measure corresponds to the breaking length data commonly reported for textile fibers.

High values of this parameter are only attainable with materials having high tensile strength and low density. These criteria apply mainly to the fibrous component, since the strength of the composite is determined almost exclusively by the fibers. The matrix serves to protect fiber surfaces from damage, distribute applied forces, and compensate for microscopic fiber fracturing. Thus, it is more important that the matrix material have a low density than that it be particularly strong.

Strong binding and high rigidity are achieved primarily by maximizing the number of covalent bonds per unit cross-section. This high concentration of bonds ("valences") can only be realized without undue increase in fiber weight if the constituent atoms are of low atomic mass.

For these reasons only a few elements can be considered candidates for the construction of high-strength fibers: those with low atomic number and covalent bonding character [3]. Beryllium can be largely excluded on the basis of its toxicity. Thus, there remain (apart from Al_2O_3) only boron, carbon, and silicon, as well as a few of their compounds with oxygen and nitrogen. Hydrocarbon and silane fibers generally possess low E moduli; their constituent hydrogen atoms occupy much space, but contribute nothing to material strength. The best results within this category of substances have been achieved with

aramide fibers, which combine benzene rings and – CONH – groups in rather strict alignment.

When one considers applications entailing the strengthening of metals, especially for use as high-temperature materials, the thermal stability of the fibrous component becomes another criterion, which limits the choice further. The best solution in a qualitative sense is graphitized carbon fibers [26], although B_4C and BN fibers of very high quality and with melting points above 2500 °C can also be prepared (by high-temperature boration of carbon fibers and high-temperature nitration of B_2O_3, respectively).

The choice is further influenced by price and production costs, factors that are highly susceptible to change in response to technological developments. Materials exist whose costs are more favorable than those of the components described above, but their properties are also less ideal. An example is mullite fiber (Al_2O_3–SiO_2–B_2O_3) produced by the centrifugal melt spinning process. Glass fibers fall at the low end of both the price scale and the thermal stability spectrum. It should be noted again that optimization of the balance of technical and economic factors is often possible with hybrid composites, such as those containing combinations of carbon and glass fibers.

Strength factors as they are actually observed, particularly in the case of graphite fibers, come very close to the theoretical values predicted from atomic bond strength data. Thus, it is unrealistic to anticipate that further significant increases will be obtained.

3.2. Behavior in Compliant Matrices [29–32]

The most easily described situation consists of a fiber composite material containing infinitely long fibers oriented in a single direction. If this material contains n_F fibers of cross-section a_F within an overall cross-sectional unit area, then the corresponding fiber volume fraction can be calculated as $f = n_F\, a_F$. When such a composite is placed under elastic stress, the extent of elongation is identical for both fiber and matrix (apart from small regions near the ends of the sample). Application of Hooke's law under these considerations illustrates the role of the modulus of elasticity E_F of the fibers. Thus, the average tension that the composite is capable of sustaining for a given elongation is

$$\sigma_c = f\sigma_F + (1-f)\,\sigma_M = [f E_F + (1-f)\, E_M]\,\varepsilon \qquad (2)$$

This can be rewritten as

$$\sigma_c = E_c \cdot \varepsilon$$

or, if the effective modulus of elasticity for the composite is expressed as E^c, it can be written as

$$E_c = f E_F + (1-f)\, E_M \qquad (3)$$

Equation (3) contains the so-called "rule of mixtures," which provides a first approximation to the behavior of a composite material. It is known, however, that this approximation can, for a number of reasons, lead to errors of ± 30 % or more in individual cases. Notice that if one assumes a fiber volume fraction of ca. 50 %, then $E_c \approx 1/2 E_F$, provided that (as is usually the case) $E_F \gg E_M$. Thus, the elastic properties of the matrix are irrelevant to the overall behavior of the composite. The fibers alone determine the strength of the whole.

Nevertheless, glass fibers and most of the other fibers that lend themselves to practical application are brittle; that is to say, they break rather than undergoing plastic deformation upon reaching some maximum load σ_F^*. This behavior is of considerable importance in the development of a composite material, because the total elongation ε (see above) at maximum load (the breaking point) remains very low due to the high E modulus of the fibers:

$$\varepsilon^* = \sigma_F^* / E_F \qquad (4)$$

At this elongation the amount of stress assumed by the matrix, determined by its elastic resilience, is correspondingly small, namely $\tilde{\sigma}_M = E_M \varepsilon^*$. The load supported by the matrix at the breaking point is thus

$$\sigma_c^* = f\sigma_F + {}^*(1-f)\,\tilde{\sigma}_M \qquad (5)$$

This composite strength increases in a linear manner from $\tilde{\sigma}_M$ as the degree of admission increases. Nonetheless, it is also necessary to take into account the fact that a nonreinforced matrix with the same cross-section $(1-f)$ has, in the

region $f = 0$, a greater strength than the composite (if it is assumed that the breakage of a high proportion of the fibers also leads to destruction of the matrix). Thus:

$$\sigma^*_{\mathrm{MN}} = (1-f)\, E_{\mathrm{M}} \varepsilon^*_{\mathrm{M}} \tag{6}$$

where $\varepsilon^*_{\mathrm{M}}$ is the breaking elongation of a sample of matrix from which a certain amount of material has been removed to create the channels that would otherwise be occupied by fibers. Figure 2 is a graph of Equations (5) and (6), clearly showing that at low volume fractions there is a decrease in overall tensile strength caused by reduction in the matrix cross-section.

Figure 2. Influence of the volume fraction on strength σ^*_{c} for a composite whose fibers are oriented in a single direction as compared to the strength σ^*_{MN} of a nonreinforced matrix of the same cross-sectionOnly if $f > f''$ is there a true strengthening of the composite relative to matrix material.

Only after a *critical volume fraction* f' has been reached does the strength begin to rise. True strengthening by fibers can only be said to occur after a volume fraction f'' has been exceeded, where f'' is defined such that above this value, the strength of the composite is greater than that of a pure matrix of comparable cross-section. Thus:

$$f'' = (\sigma^*_{\mathrm{M}} - -\tilde{\sigma}_{\mathrm{M}}) \,/\, (\sigma^*_{\mathrm{F}} - -\tilde{\sigma}_{\mathrm{M}}) \tag{7}$$

In the event that the E modulus of the fibers is very large, $\tilde{\sigma}_{\mathrm{M}} \ll \sigma^*_{\mathrm{F}}$ and, in fact, $\ll \sigma^*_{\mathrm{MN}}$. Equation (7) can then be approximated by:

$$f'' \approx \sigma^*_{\mathrm{M}} / \sigma^*_{\mathrm{F}} \tag{7a}$$

Thus, if the fibers have a tensile strength 10 times that of the matrix, the degree of admission must be at least 10 % for a strengthening effect to be achieved. This would appear readily attainable, but certain limitations must also be recognized. For example, the tensile strength of a composite is reduced when, in the interest of improving transverse strength, uniaxially incorporated fibers are replaced by a fiber network. Moreover, defects are always present in the fibers of a real material. It is true that premature breakage of individual fibers will be somewhat confined as a result of localized crack branching and plastic microdeformation of the matrix. At the same time, however, the risk of crack spreading is increased if breakage of one fiber causes transmission of critical loads through the matrix to adjacent fibers. This risk makes it mandatory that an ample volume of matrix material be present even at high fiber volume fractions in order that it may serve to maintain the integrity of the composite and prevent the spreading of breaks from one fiber to another. Furthermore, the Weibull statistical probability of fiber breakage and the rate of subcritical expansion of cracks within the fibers must be known if one is to make a realistic estimate of the value of σ^*_{F}. In other words, account must be taken of the distribution of microdefects both in the fibers and at their surfaces.

All of these aspects of the subject have been thoroughly discussed [29–32]. The same is true for metal fibers, which undergo plastic deformation when subjected to stress above the flow limit, consequently become stiffened, and then break only when subjected to relatively high degrees of elongation. The matrix, too, is considerably stretched in the process, so that its fracture properties must also be taken into account. It is fundamentally true that the inherent strength of the matrix is here better utilized. The transmission of forces through a matrix by short fibers is thoroughly discussed in the literature [33], [34]. In this case, transverse stress along the fiber encasement surfaces plays a decisive role.

3.3. Behavior in Brittle Matrices

A brittle matrix represents a different situation, one in which the task of fibers is not to increase elastic strength or to raise the tensile strength relative to the matrix material. Instead, fibers are

expected to counter what is the principal disadvantage of a brittle matrix: the tendency for cracks to be rapidly propagated and – unlike metals – for breakage to occur due to the absence of damage-limiting plastic deformation in the vicinity of the crack front.

The "ductilization" that results from incorporating fibers into ceramic materials is a consequence of the fact that any cracks that form in the matrix transverse to the direction of stress fail to penetrate into the fibers: the lower *E* modulus (greater ductility) of the fibers allows them initially to undergo elongation (Fig. 3). In other words, those fibers that happen to lie in the direction of stress effectively "bridge" the crack and exert a force counterbalancing the opposing stress. Elastic elongation does lead automatically to cross-sectional contraction of the fibers, however, just as with the plastic stretching of metal fibers. Consequently, fiber separation from the matrix can occur in strain-free regions at the edge of a crack. This results in additional fiber length becoming available to accommodate further energy-consuming length changes, thus permitting the crack to open wider and increasing the potential for its further growth.

Figure 3. Elastic – plastic bridging of a crack and "pull-out" of fibers within a matrix at the onset of crack formation

Whenever short fibers are utilized, the probability (which can be easily quantified) exists that ends of fibers will be present in the vicinity of the walls of a crack. Thus, there arises the possibility that fibers will be pulled out of the matrix as the crack grows and cross-sectional contraction occurs. This process, known as "pullout," also consumes energy in the form of friction with the walls. The extent of the extra work expended in broadening of main cracks is clearly demonstrable with or without pullout. It appears as an increase in the effort required to break a sample (equal to the integral under the corresponding stress/elongation curve), and leads to an increase in ductility.

The following Chapters deal only with Advanced Composites; the others are separate keywords listened at the beginning of this article.

4. Materials Used in Advanced Composites

Approximately two decades ago, to meet the requirements of advanced military systems, a number of low-density fibers were produced that exhibited both high specific stiffness and high specific strength. In the ensuing years, the category of high-performance fibers has grown to include such diverse materials as carbon (graphite), p-aramid, boron, silicon carbide, alumina, silica, and glass. Incorporating one or more classes of these high-performance filaments in a suitable matrix to achieve properties that approach those of steel or aluminum produces a specialized class of composite materials, herein called advanced composite materials, that exhibit physical and structural properties not attainable with conventional engineering materials. The matrix or bonding agent can be a thermosetting resin, a thermoplastic resin, a metal, or a ceramic material.

On a functional basis, advanced composite materials may be described as a specialized class of composite materials that contain a high volume concentration of continuous high-performance fibers and, therefore, exhibit very high specific strength (strength/weight) and very high specific modulus (stiffness/weight).

The choice of production methods and most of the environmental properties of advanced composite materials are a function of the matrix material rather than the high-performance fiber. In this respect, resin matrix composites have the general characteristics of reinforced plastics, metal matrix composites behave like metals, and so forth. While there is much technical interest in the development of metal, ceramic, and carbon matrix advanced composite materials, resin matrix materials dominate the technology and commercial use of advanced composite materi-

als. The predominance of resin matrix systems is due to a number of reasons, which include:

1) The relatively low temperatures involved in the fabrication of resin matrix materials as compared to carbon, ceramic, or metal matrix materials, thus reducing the problems of internal stresses induced by differences in the coefficients of thermal expansion of the components and/or reaction products between components
2) The direct applicability or adaptability of fabrication technology developed for glass fiber reinforced plastics to the fabrication of advanced composite materials systems.

Carbon, ceramic, or metal matrix composites are being developed principally for use in high-temperature environments hostile to resin matrix materials, or in applications that require characteristics not attainable with organic resins, such as electrical conductivity or toughness of the level attainable with metal matrix materials.

4.1. Reinforcing Fibers

In general, reinforcing fibers used in advanced composite materials can be characterized as being light, stiff, and strong. These properties are usually exhibited by materials on the basis of the elements Be, Mg, B, Al, C, Si, Ti. Most of these relatively light elements form thermally stable covalent bonds, which are inherently stiffer and stronger than compounds formed through metallic or ionic bonds. However, many of these materials are quite brittle in bulk form because of the presence of internal or surface flaws. The probability of internal flaws, which detract from the potential strength of these materials, is minimized when the material is used in a fibrous form.

Of the elements listed above, carbon and silicon are the most important in terms of the composition of commercially available high-performance fibers. These fibers can be considered to belong to one of the three following broad families of materials: carbon, organic resins, and inorganic compounds. Within each family, several classes of high-performance fiber materials have been developed that satisfy the basic criteria of low density, high strength, and high stiffness to varying degrees. Each of these classes of fiber materials is unique in that it offers a different combination of properties and characteristics. The various fiber classes exhibit different combinations of mechanical properties, physiochemical properties, electromagnetic properties, and economic characteristics (cost and availability).

4.1.1. Carbon Fibers (→ Fibers, 5. Synthetic, Inorganic)

Carbon fibers are the predominant high-strength, high-modulus reinforcing fiber used in the manufacture of advanced composite materials. Carbon fibers are made by the pyrolytic degradation of a fibrous organic precursor. In the process, an organic polymeric fiber is heated under tension and in an inert atmosphere to a very high temperature to drive off the volatile constituents. The residual carbon atoms tend to orient themselves along the fiber axis into graphitic crystallites to form a high-strength, high-modulus fiber. The composition of the precursor and the time – temperature history of the fiber establish the properties of the carbon fiber product. In general, as the processing temperature to which the fiber is exposed increases, the extent of crystallite orientation parallel to the fiber axis increases, and thus the fiber modulus increases. Because of greater sensitivity to flaws, this increase in modulus is usually accompanied by a decrease in strength. Because of the high degree of internal structure orientation, graphite fibers are strongly anisotropic. Their transverse tensile and shear moduli are usually an order of magnitude lower than the axial modulus.

A good carbon fiber precursor has the following characteristics:

1) Its chemical structure favors the formation of an aligned graphitic carbon structure during pyrolysis
2) A high carbon fiber yield is obtained
3) Fiber integrity is maintained during the pyrolysis process
4) The fiber is strong enough to be handled during all phases of the pyrolysis process
5) It should be inexpensive and readily available from various commercial sources.

The first characteristic is essential to obtain the required mechanical properties. The others,

particularly achievement of a high carbon yield, are important for reasons of practicality and cost. Obtaining a high carbon yield is necessary not only to minimize raw material consumption, but also to reduce the volume of off-gas that is generated and must be treated.

The organic materials that have best satisfied these criteria to date are rayon (cellulose acetate), polyacrilonitrile (PAN), and petroleum pitch.

Rayon-Based Carbon Fibers. Carbon fibers based on rayon are now mainly of historical interest. The commercial use of carbon filaments produced by the pyrolysis of cellulose dates back to 1880 when THOMAS EDISON patented the incandescent electric lamp [35]. The development of methods of producing rayon-based carbon fibers that warranted their use as reinforcements in structural composites is a much more recent event, dating back to the mid-1950s and early 1960s. Key discoveries included recognition of the need to apply stress to the fiber prior to and during carbonization, which resulted in the initial development of high-modulus carbon fibers. These efforts led to the commercial production of Thornel 25 by Union Carbide. This material exhibited an average modulus of 25×10^6 psi (170 GPa) and an average tensile strength of 184×10^3 psi (1.27 GPa). As the process became more refined with time, Union Carbide was able to introduce rayon-based carbon fibers with improved performance characteristics, such as Thornel 50, and Thornel 75, which respectively exhibited an average modulus of 57×10^6 psi (380 GPa) and 75×10^6 psi (520 GPa) and average tensile strengths of 315×10^3 psi (2.17 GPa) and 385×10^3 psi (2.65 GPa) [36]. High-modulus rayon-based carbon fibers are, however, expensive to produce because of the low carbon yields (10 – 30 %) and because of the extremely high temperatures (>2800 °C) required for the "stretch graphitization" operation needed to attain moduli in excess of 100 GPa. Because of their high price (>$ 600/kg in the early 1970s), they have not been able to compete with lower cost carbon fibers that are based on other precursor materials.

PAN-Based Carbon Fibers. Most of the carbon fibers that are currently commercially available are obtained by the pyrolysis of polyacrylonitrile (PAN), an atactic, linear polymer that contains nitrile pendant groups attached to

a carbon – hydrogen backbone. This technology is principally based on the work of SHINDO et al. in Japan [37] and of WATT and JOHNSON of the Royal Aircraft Establishment in Great Britain [38]. The essential elements of the production of PAN-based carbon fibers are outlined in Fig. 4. In the process, bundles (tows) that may contain from ca. 1000 to 320 000 individual fibers, each ca. 10 µm in diameter, are passed, while under tension, through a series of ovens where the temperature and atmosphere are closely controlled. The time – temperature history of the fiber establishes the characteristics of the carbon fiber produced: the higher the temperature, the higher the degree of graphitization and the higher the modulus of the resulting carbon fiber.

Figure 4. Graphite fiber process outline

Table 1. Representative properties of standard PAN-based carbon fibers

Fiber type Nominal designation	Type I High strength	Type II High modulus	Type III Ultrahigh modulus
Carbon content, wt %	92 – 94	>99	>99.9
Specific gravity	1.7 – 1.8	1.8 – 1.9	1.9 – 2.1
Filament diameter, µm	7 – 8	7 – 8	8 – 9

Tensile strength, GPa	2.5 – 3.5	2.2 – 2.4	1.8 – 1.9
Tensile elongation, %	1.2 – 1.4	0.6 – 0.7	0.3 – 0.4
Toughness, MPa	20	7.5	3
Electrical resistivity, µΩ/m	15 – 18	9 – 10	6 – 7
Longitudinal CTE *, $10\,mm^{-1}\,K^{-1}$	−0.5	−0.7	−0.9 (est.)
Range of available tow counts, 1000 fibers/bundle	1 – 320	1 – 12	<1
Price range, 1985 $/kg	40 – 300	90 – 1000	>300

* CTE = coefficient of thermal expansion.

Worldwide, there are currently over a dozen producers of PAN-based carbon fibers, each of whom offers a number of specific products. Most manufacturers offer a high-strength product (type I carbon fiber) and a high-modulus product (type II carbon fiber), with some manufacturers also offering an ultrahigh-modulus product (type III carbon fiber). Representative properties for these materials are given in Table 1. As can be noted from this table, there is a close correlation between carbon content and physical properties. Strain to failure is low for carbon and all types of carbon fibers, but especially for the higher modulus products. This makes the handling of carbon fibers difficult and is one of the major limitations of the products listed in Table 1. Carbon fibers differ from other high-perfomance reinforcing fibers because they are good conductors of electricity. They also exhibit unusual thermal expansion characteristics, since the coefficient of thermal expansion is negative along the fiber axis while being positive in the transverse directions.

The price of commercial PAN-based carbon fibers ranges from ca. $ 40/kg to $ 1000/kg (1986). These prices are mainly a function of fiber modulus and the number of filaments in a yarn bundle (end count). Type I (high-strength) fibers are less expensive than type II (high-modulus) fibers, in part because processing costs are lower and in part because they are manufactured in higher volumes. Type III (ultrahigh-modulus) fibers are expensive speciality materials. For any fiber type, price is also a strong function of end count. High end count material (40 K or more) is significantly less expensive than low end count material (12 K or less). This price differential is a reflection of the fact that plant production capacity is directly proportional to end count. Thus, production costs increase as the end count decreases. However, pyrolyzing low end count bundles results in a more uniform product. In most critical applications, high end count material is rarely used.

The low strain to failure characteristics have been the major limitation of the standard PAN carbon fibers listed in Table 1. High-strain carbon fibers are now available that exhibit tensile elongations of ca. 1.7 – 1.8 %, as shown in Table 2. These fibers are not only unusually strong, but also much easier to handle, which facilitates the fabrication of composite parts.

Table 2. Representative properties of high-strain type I PAN-based carbon fibers

Carbon content, wt %	92 – 94
Specific gravity	1.7 – 1.8
Filament diameter, µm	5 – 8

Tensile strength, GPa	4.0 – 4.7
Tensile elongation, %	1.7 – 1.8
Toughness, MPa	34 – 42
Longitudinal CTE, $10\,m\,m^{-1}\,K^{-1}$	−0.5
Range of available tow counts 1000 fibers/bundle	6 – 12
Price range, 1985 $/kg	90 – 100

Pitch-Based Carbon Fibers. Petroleum pitch is that fraction of the petroleum barrel that is uneconomical to further process into light hydrocarbons because of its tendency to carbonize and interfere with processing operations such as catalytic cracking. Because petroleum pitch is a high carbon content, readily available, and

low cost material, interest has been growing in its use as a precursor material in an attempt to reduce the manufacturing cost of carbon fibers.

Petroleum pitch must be purified and preconditioned to produce high-performance carbon fibers. An important step is the development of a liquid crystalline phase (mesophase) prior to spinning to form fibers with a high degree of preferred orientation. These preliminary operations add substantially to the fabrication costs.

4.1.2. Organic Fibers (→ Fibers, 4. Synthetic, Organic)

The measured tensile strength and modulus of most natural and synthetic organic fibers are typically less than 1 and 10 GPa, respectively. These values are significantly lower than the theoretical values of the maximum tensile strength (>20 GPa) and modulus (>100 GPa) calculated on the basis of force constants of bonds in the polymer chain and crystal extensions observed by X-rays on stressed fibers [39]. A number of polymeric fibers are now commercially available, whose strength and modulus more closely approach these theoretical values and which are high enough for these materials to be considered as reinforcements for advanced composites. As compared to other textile fibers, these high-strength, high-modulus materials all exhibit a high degree of molecular orientation and chain alignment. High-performance organic fibers of this class that have been commercialized to date include *p*-aramids, ultrahigh molecular mass polyolefins, and certain classes of polyesters.

***p*-Aramid Fibers.** Aromatic polyamides or aramids were introduced initially in the early 1960s to meet the need for fibers with improved heat and flammability resistance. The first example of this class of compounds was poly(*m*-phenyleneisophthalamide), which is sold commercially by Du Pont under the trademark Nomex. In the early 1970s, Du Pont introduced aramid fibers under the trademark Kevlar, based on para-substituted aromatic polyamides, most notably poly(*p*-phenyleneterephthalamide) (PPD-T), which is a condensation product of *p*-phenylenediamine and terephthalic acid.

Other aramid fibers have been more recently introduced to the market by Enka (Netherlands) and Teijin (Japan).

Because of its rigid chain structure, PPD-T can exhibit liquid crystalline behavior in solution. The rodlike molecules of these materials can aggregate in nematic, ordered domains. When liquid crystalline solutions of these materials are subjected to shear, these ordered domains tend to be oriented in the direction of flow. When passed through a spinneret, these liquid crystalline solutions retain the high degree of orientation imparted by the spinning operation, leading to as-spun fibers with extraordinary levels of crystallinity and orientation.

As-spun fibers obtained by the spinning of a 20 % solution of PPD-T in 100 % sulfuric acid exhibit a crystalline orientation angle of ca. 12° (as determined from wide-angle X-ray diffraction) and a modulus of ca. 72 GPa. Heat treatment increases the degree of crystalline alignment. Heat-treated fibers have an orientation angle of ca. 9°, and a tensile modulus of ca. 120 GPa.

Du Pont markets several types of fibers under the Kevlar aramid trademark that offer different combinations of properties to satisfy the requirements of a variety of end use requirements. The major products are Kevlar, Kevlar 29, and Kevlar 49 aramid fibers. The major end uses of these materials are outlined in Table 3. Selected physical properties of Kevlar 49 and of Kevlar 29, the two products of interest in terms of plastics reinforcements, are presented in Table 4. The stress – strain graph for Kevlar 29 is nonlinear. At failure, its tensile modulus is about 20 % higher than the initial value reported in the table.

Kevlar 49, because of its higher modulus, is the member of the Kevlar aramid product family normally used in advanced composites. Although Kevlar 49 behaves elastically in tension, it exhibits nonlinear characteristics under compressive stress. The application of compressive stress results in formation of structural defects called kink bands and eventual ductile failure [40]. The onset of this behavior occurs at compressive yield strains of ca. 0.3 – 0.5 %. This phenomenon has been attributed to a molecular rotation of the amide carbon – nitrogen bond from the normal extended trans configuration to a kinked cis configuration. This results in about a 45° bend in the chain, which propagates to form a kink band across the fiber.

As a result of this unusual behavior under compression, the use of *p*-aramid fibers in applications subject to high-strain compressive or flexural loads is limited. At the same time, however, because of their ductile response under compression, *p*-aramid fibers are inherently tough materials that exhibit good damage tolerance and energy absorption characteristics.

Polyolefin Fibers. The high degree of molecular orientation that results in a well-defined crystalline structure, and the corresponding high-modulus, high-strength properties, can also be obtained by the imposition of a very high degree of plastic extensional deformation on a polymer in the solid state. When this method is applied to ultrahigh molecular mass polyethylene, which exhibits a very high degree of crystallinity, very strong and stiff fibers can be prepared [41]. Allied has developed a high-strength, high-modulus polyethylene fiber, trademarked as Spectra 900, for tensile applications such as ropes and cordage. It may also have potential use in polymer matrix composites. Room-temperature properties of this fiber are presented in Table 5. While this fiber exhibits superior mechanical properties at ambient temperature, its utility decreases rapidly with increasing temperature above 50 °C due to the relatively low melting point of the polymer. A noticeable decrease in tensile properties occurs above 50 °C. At 120 °C, the tensile strength is approximately half the value at ambient temperature, with elongation increasing proportionally.

4.1.3. Inorganic Fibers (→ Fibers, 5. Synthetic, Inorganic)

Even though the densities of inorganic fibers are significantly higher than those of carbon and polymeric fibers, these materials are of interest

in the preparation of advanced composite materials because of their stability at high temperature and their compatibility with metal and ceramic matrices, which are also inorganic materials. In addition, any listing of reinforcing fibers for advanced composite applications must include glass fibers because of their low cost and economic importance as the primary fibrous reinforcing material used by the plastics industry.

Glass Fibers. Glass fibers, also called fiberglass, have become a major product since their commercial introduction by Owens-Corning Fiberglass Corp. in 1939. Worldwide, the reinforced plastics and composites industry is currently estimated to use over 500 000 metric tons annually of glass fibers.

Glass fibers are prepared by melting a suitable mixture of raw materials (silica sand, limestone, boric acid, alumina, etc.), extruding the molten glass through a platinum spinneret and cooling the streams to form a multitude of individual glass fibers, which are then lubricated and mechanically gathered into strands. Glass fibers produced in this manner are amorphous and isotropic.

The principal grades of glass fibers used in composite applications are E-glass (E: electrical) and S-glass (S: strength). A third type, C-glass (C: corrosion), is used where resistance to acid corrosion is particularly important. The nominal compositions of E-glass and S-glass are presented in Table 6. Representative properties of these grade of glass fibers are presented in Table 7. Glass fibers generally have a high strength: weight ratio, but their moduli, which are in the range of aluminum alloys, are significantly lower than those of most of the other high-performance fibers considered in this chapter. Glass fibers are extremely sensitive to abrasion damage. They are coated with protective sizings to minimize this problem. Sizing materials also lubricate the fiber and promote its resin adhesion.

E-glass is the most common grade of fibrous glass used by the plastics industry. While originally introduced for electrical applications because of its dielectric and loss tangent properties, E-glass is used in many nonelectrical applications because of its combination of mechanical properties and low cost. E-glass is the only reinforcing fibrous material available at a price of $ 1/kg.

S-glass is a high-strength glass initially developed for military applications. Its modulus is about 20 % greater than that of E-glass, and it is about one-third stronger. The creep rupture resistance of this material is significantly better than that of E-glass, and it is about one-third stronger. It is significantly less susceptible to acid corrosion than E-glass. The failure energy of S-glass is high, making it a very tough fiber.

S-2 glass is a fiber of the same chemical composition as S-glass that was developed for commercial applications. The primary difference in the two products is the sizing on the fibers. The cost of S-2 glass fibers is, however, significantly lower than that of S-glass fibers because they are not subject to the stringent and expensive quality control procedures imposed by military procurement requirements.

High-Silica and High-Quartz Fibers. A number of high-silica (>95 % silica) and high-quartz (>99.95 % silica) fibers, which melt at a higher temperature than glass fibers, have been developed for extreme-temperature textile applications. At lower temperatures, the mechanical properties of this family of fibers are not substantially different from those of glass fibers. They exhibit superior electric properties, in terms of exhibiting an even lower dielectric constant and a lower power dissipation factor than E-glass. The high-temperature properties of silica fibers are of little value in resin matrix composites, where temperature limitations are imposed by the thermal resistance of the matrix material. Because they are significantly more expensive than glass fibers, high-silica and high-quartz fibers are rarely used as composite reinforcing fibers, except in specialized electronic applications, where an extremely low dissipation factor is required.

Alumina-Based Fibers. A number of fibers with a high alumina content (>60 wt % alumina) have been developed both for high-temperature textile applications, where they compete with high-silica and high-quartz fibers, and as reinforcements for metal matrix and ceramic matrix composites. The nominal composition and representative properties of five such materials that are currently commercially available are listed

Table 6. Chemical composition (in wt %) of inorganic oxide fibers

in Tables 6 and 7. These fibers are generally prepared by extruding an aqueous or organic precursor gel through spinnerets, drying the resulting fibers to remove most of the liquid phase, and then subjecting the resulting filaments to high-temperature (>1200 °C) heat treatment to form a continuous refractory yarn. ICI's Saffil fibers have a δ-alumina crystal phase, whereas Du Pont's FP fibers are polycrystalline α-alumina. Saffil alumina is not available as continuous filaments, but only as fibers 1 – 5 cm long (in mat form) or less (in bulk and milled form).

The Sumitomo and 3M Nextel fibers are alumina-rich mixtures of alumina and silica and exhibit properties intermediate to those of pure silica and pure alumina fibers.

The high-alumina fibers all exhibit superior high-temperature properties, as exemplified by the fact that for all these fibers, increasing temperature from ambient to 1100 °C results in a reduction in tensile strength of less than 10 %. These fibers are claimed to be able to sustain exposure temperatures that range from 1200 °C to 1600 °C. At 1100 °C, these fibers are wetted by and stable in molten light metal alloys, such as those of aluminum and magnesium. Thus, these fibers are of interest as reinforcing materials for metal matrix composites.

Silicon Carbide Fibers. Since the 1960s, there has been significant interest in development of continuous carbide, nitride, and boride fibers and filaments as reinforcing fibers for high-temperature structural materials. Of these materials, silicon carbide fibers offer the most promise and are currently the most fully developed. Silicon carbide filaments are of interest because of their thermal stability, oxidation re-

sistance, superior mechanical properties at elevated temperatures, and compatibility with most molten metals, as well as with many ceramic materials. Silicon carbide is currently available in two different types of continous filaments, as well as in whisker form. These fibers, as well as isotropic SiC powder, are all being actively examined as reinforcements for a variety of metal matrix and ceramic matrix applications.

Because of the refractory nature of silicon carbide, silicon carbide fibers cannot be produced by consolidation from the melt or by sintering. The silicon carbide fibers that are currently available are produced by very different process routes. Avco Corp. produces large-diameter silicon carbide filaments by a vapor chemical deposition process, Nippon Carbon Corp. produces finer diameter continuous filaments by the pyrolysis of polycarbosilane polymers, and Arco Chemical Co. produces silicon carbide whiskers by the pyrolysis of rice hulls.

Avco's CVD process is very similar to the one it developed for the production of boron filaments. Boron filaments, which were major reinforcing fibers about a decade ago, have been displaced by carbon and aramid fibers in resin matrix composites, principally because these fibers are expensive ($ 700/kg) and difficult to handle. In the Avco process, silicon carbide filaments are produced by reducing a blend of methyltrichlorosilane and methylhydrogendichlorosilane with hydrogen in the presence of an electrically heated, continuously moving carbon substrate filament. Representative properties of these filaments are given in Table 8.

The original impetus for developing SiC filaments was to obtain a fiber better suited than boron for incorporation in metal matrix composites. Boron rapidly loses its strength at temperatures above 600 °C and is unsuitable for high-temperature applications. Furthermore boron reacts with molten metals, such as aluminum, which makes the fabrication of boron-reinforced metal matrix composites by liquid infiltration or standard casting techniques not feasible. Silicon fibers made by this process are potentially less expensive than boron fibers because the rate of deposition is faster and lower cost raw materials are required. The price of $ 1100/kg (1986) reflects the developmental status of these fibers. Avco projects that in production quantities, the price of these fibers would be less than $ 300/kg.

Nippon Carbon Co.'s silicon carbide filaments are produced by the pyrolysis of a carbosilane polymer precursor, a process originally developed by Yajima of Tohoku University [42]. Yajima discovered that polydimethylsilane polymers, obtained by condensing dimethyldichlorosilane in an autoclave at ca. 450 °C, could be melt spun into fibers, which when subsequently pyrolyzed at ca. 1300 °C in an inert atmosphere were transformed into high-strength, high-modulus fibers that were predominantly β-silicon carbide ($>$ 80 wt %) and carbon. In spite of their carbon content, these fibers were observed to be oxidation resistant and wetted by molten metals. It was subsequently observed that the physical properties of the silicon carbide fibers were improved by slight modifications in the composition of the polycarbosilane precursor. In particular, the addition of diphenyldichlorosilane and of boron-modified silanes to the condensing reaction mixture was observed to have a beneficial effect on fiber properties. The properties of these silicon carbide fibers, which are marketed under the trademark Nicalon, are also given in Table 8. According to the Dow Corning Co., the United States distributor of these fibers the price of these fibers in production quantities could drop from the present level of $ 500/kg to ca. $ 220/kg.

4.1.4. Reinforcement Geometry

The fiber diameter of the various fibers discussed in the previous sections of this chapter is in the 5 – 20 µm range. Exceptions to this are the silicon carbide and boron filaments produced by chemical vapor phase deposition, which have a diameter of ca. 140 µm (Avco). As a result, these filaments are neither combined in strands nor treatable by standard textile fiber processes. Fibers of small diameter range are flexible enough to be amenable to processing by many standard textile operations in spite of their high modulus. At the same time, fibers of this diameter range are too large to be aspirated into the human respiratory tract, and thus, do not present the environmental health hazards associated with fibrous materials, such as asbestos. Most of these fibers also have a circular cross-section. Notable exceptions are rayon-based carbon fibers, which are crenulated,

Table 8. Representative properties of SiC fibers

* Sublimes

and certain PAN-based ultrahighmodulus carbon fibers (e.g., Celion 70), which are bilobar.

Fibers in the above diameter range are too fragile to be handled individually and are only available as multifilament strands. The reinforcing materials used in most advanced composite applications typically have a tow count of 200 – 12 000 filaments per strand. It should be noted that carbon fibers are also available in much higher tow counts, as noted in Table 1. Carbon fiber tows with a high tow count are not commonly used in the manufacture of advanced composite parts, even though they are less expensive than low end count carbon tows. In general, low end count strands are preferred as reinforcements for critical applications of advanced composite materials. The higher the tow count, the greater the variation in filament properties, and the more difficult it becomes to assure uniform contact between the matrix and the individual filaments.

Strands of reinforcing fibers can also be woven into flat fabrics, or three-dimensional woven or knitted fabrics, or even braided shapes, by slight modifications of standard textile machines. So-called structural fabrics, which contain one or more reinforcing fibers, are available in a wide variety of weaves and fabric weights.

4.2. Matrix Materials

The matrix of an advanced composite is the continuous phase that binds the fibers together so that they can act in concert. The major characteristics required of a matrix material are that it be:

1) Chemically compatible with the reinforcing fibers
2) Compatible with the manufacturing methods used to fabricate the desired advanced composite component
3) Environmentally stable under conditions of use of the advanced composite component.

The matrix material is the primary influence on mechanical properties of interlaminar shear strength and compression and flexural strength, especially at high temperature. The matrix also dictates the processibility of the composite, and its environmental resistance. Since the processibility and the environmental properties of advanced composite components depend to a significant extent on the characteristics of the matrix material, no single ideal matrix material exists that satisfies the multitude of requirements imposed by different applications. Thus, advanced composites have been prepared with a

diversity of matrix materials, which include organic polymers, carbon, metals, and ceramics.

Polymeric materials historically have been the predominant matrix materials used in advanced composites. Such as high-performance fiber-reinforced epoxy resins. Many other high-performance fibers are now combined with many other thermosetting and thermoplastic resins.

Thermosetting Resins. Thermosets are those resins which in the presence of a catalyst, heat, radiation, and/or pressure undergo an irreversible chemical reaction, or cure. Prior to cure, thermosets may be liquid or made to flow under pressure to any desired form. Once cured, they cannot be returned to the uncured state, and can no longer flow. This cure reaction can be either an addition reaction, such as the free radical polymerization of unsaturated groups, or a condensation reaction, which occurs as a result of the stepwise combination of different functional groups. If the volatile byproducts can be removed, superior properties can be attained with condensation polymers. This generally requires long, high-temperature cure cycles.

Epoxy Resins (→ Epoxy Resins). Epoxies are, by far, the matrix materials most commonly used in advanced composite materials. The main reason is the good balance of properties obtained with relative ease of handling and processing.

Epoxies are generally obtained by reacting epichlorohydrins (ECH) with molecules containing active hydrogen, such as phenols, amines or acids, followed by dehydrochlorination:

Most of the commercial epoxies are based on bisphenol A; higher functionality resins for higher temperature are based on aminophenols, diaminodiphenyl methane, triphenol methane, or novolaks.

Epoxies can be cured either by ionic homopolymerization of the epoxy groups or by reaction with suitable polyfunctional curing agents, such as primary or secondary amines, anhydrides, phenols, acids, or dicyandiamide. Some typical curing agents are:

4,4′ - Diaminodiphenylmethane

4,4′ - Diaminodiphenylsulfone

4,4′ - Diaminodicyclohexylmethane

Dicyandiamide

Imidazole

2,5 - Dimethyl hexan - 2,5 - diamine

Cure and processing behavior are governed by structure and choice of components. Aliphatic amines allow ambient temperature curing, whereas slow-reacting, aromatic amines, such as diaminodiphenyl-sulfone (DDS), require a high temperature to cure.

The range of properties attainable for neat (unfilled), cured epoxy resins of different structure are summarized in Table 9. In general, increasing the concentration of aromatic rings and cross-links tends to improve resin properties such as thermal stability, chemical resistance, and rigidity, but lowers the strain to failure (increased brittleness).

Table 9. Property values of unfilled cast epoxy resin systems [43]

Property	Typical value at 23 °C (73 °F)
Specific gravity	1.2 – 1.3
Rockwell hardness	M100 – M110
Impact strength (notched bar, Izod test) J/m of notch	0.1 – 1.0

System = Narmco 5208, wet: after 50 h water boil (3.1 % moisture pickup)
Note: 1 psi = 6.895 × 10^3 Pa; 1 ksi = 1000 psi

Most of the epoxy resins used by the aerospace industry in advanced composite structures, which must withstand exposure to high temperature (350 °F = 177 °C), are highly cross-linked aromatic resins. The properties of a commercial epoxy resin, which has been accepted for high-temperature composite applications, are given in Table 10. The major performance limitations of materials of this class are their low toughness and the significant loss in mechanical properties at high temperatures, particularly in the presence of moisture, as shown in Figure 5.

Bismaleimides. Bismaleimides are synthesized by the reaction of maleic anhydride with primary aromatic diamines and subsequent cyclodehydration of the intermediate thus formed. The double bonds can be reacted further by copolymerization with suitable comonomers or by a Michael-type addition of amines, for example, [48].

Bismaleimides offer high glass transition temperatures and good aging stability and flammability characteristics. These resins are still fairly brittle and exhibit limited high-temperature (>350 °C) stability. Significant interest in these resins exists because they may be modified or formulated to achieve better environmental resistance (e.g., better properties under hot/wet conditions) than accepted epoxy resins while retaining most of the processibility characteristics of epoxies. Representative properties of a commercial bismaleimide resin are given in Table 10.

Polyimides (→ Polyimides). Polyimides are a class of resins that can withstand contin-

uous exposure in air at temperatures above 300 °C. These materials have become of practical interest because they are more processible than most other resin systems that are stable at high temperature. Polyimide resins have evolved from early amic-acid type condensation products in high-boiling solvents (such as *N*-methylpyrrolidone). These were difficult to process and tended to form porous laminates because of the subsequent condensation of volatile reaction byproducts which could not be totally removed from the resin. Subsequent developments have led to resins in which final cure is obtained by addition-type reactions, which do not emit volatile byproducts [49]. Examples include PMR-type resins, initially developed by NASA Lewis Research Center. These entail the in situ condensation of an imidized prepolymer on the reinforcing fibers at a temperature of 150 – 220 °C. The composite is then cured by cross-linking via a retro-Diels – Alder reaction at 300 – 350 °C. More recently, a family of condensation polyimides with a flexible diamine has been developed by Du Pont. These materials have the potential to be prepolymerized and handled like thermoplastics; thus, they should provide a good processing balance [54].

Ethynyl-Terminated Resins. Ethynyl-terminated resins are another promising class of high-temperature thermosetting resins. A very stable thermosetting resin is obtained by the high-temperature polymerization and cyclotrimerization of terminal ethynyl groups on resin oligomers. This intramolecular cyclization (IMC) [46] results in the formation of benzene rings as the cross-link sites. Ethynyl-terminated resins have been prepared with a wide range of backbones, including polyimides and epoxies. These materials produce thermosets with high toughness and thermal and oxidative stability, low water absorption, and versatile handling and processing characteristics. Representative properties of a commercial resin of this type (National Starch and Chemical Corps., Thermid 600) are given in Table 10.

Other Thermosets. Some of the oldest and most widely used thermosets are generally not considered as suitable matrix materials for advanced composite materials. Unsaturated polyesters are obtained by condensation of unsaturated dicarboxylic acids with polyethylene or polypropylene diols. These resins are then cross-linked by radical copolymerization of the double bonds along the chain with suitable comonomers such as styrene, divinyl benzene, etc. Because of their low cost, unsaturated polyesters are extensively used in the manufacture of glass fiber reinforced plastic parts (→ Reinforced Plastics). However, this class of polymers finds little application in advanced composites because of its relatively poor thermal resistance (i.e., low glass transition temperature) and low mechanical properties, as indicated by the data presented in Table 10. Vinyl ester resins are obtained by reacting epoxies with methacrylic acid to form a bismethacrylate. Although the double bonds of this oligomer can be cured without comonomers, it is generally diluted with comonomers similar to those used in conjunction with unsaturated polyester resins. Properties and the cost of the vinyl esters generally lie between those of unsaturated polyesters and epoxy resins, and can be varied to meet specific requirements in this range. Phenolic resins are made by condensation of phenols with aldehydes, such as formaldehyde, to form mixtures of

hydroxymethylphenols. Resol or novolak type resins are obtained, depending on the stoichiometric ratio of monomers. These resins can be cross-linked by heat, by acidic catalysts, or by the addition of cross-linking agents, such as hexamethylenetetramine. During curing, the material condenses further to form a methylene-bridged three-dimensional network. Water, which is given off as a byproduct, tends to form voids, which result in relatively poor mechanical properties. However, phenolic resins are important in the manufacture of carbon fiber reinforced carbon matrix composites, which are obtained by the pyrolysis of carbon fiber reinforced phenolic resins.

Thermoplastic Resins. Thermoplastics are materials which are normally solids at room temperature, which melt or soften when heated to a sufficiently high temperature, and which become solid again when cooled. This cycle can be repeated. As a result, it is usually easier and less expensive to fabricate a complex part out of a thermoplastic resin than with a thermosetting resin. Thermoplastic resins lend themselves to rapid processing and to the formation of complex parts by processes such as injection molding, extrusion, and thermoforming. The mechanical properties at ambient temperature of many commercial thermoplastics are comparable to those of thermosets. Thermoplastics are generally more ductile and tougher than thermosets. Indeed, for many common applications, thermoplastics are the material of choice, as evidenced by the high-volume use of polyolefins, vinyls, polyamides, polyacrylics, polyesters, etc.

The ability of thermoplastics to be deformed by heat also has deleterious effects. The creep resistance of most thermoplastics at an elevated temperature is lower than that of thermosets. This has been a serious impediment to their wider use in structural applications. Furthermore, as a class, thermoplastics also tend to be more susceptible than thermosets to solvent attack. Representative properties of selected standard thermoplastics are presented in Table 11.

Short-fiber-reinforced thermoplastics have been in use for a number of years, but there have been relatively few applications of continuous fiber reinforcement. As a consequence, there has been relatively little use made of thermoplastics in the formulation of advanced composites. This situation is now changing for two reasons. First, thermoplastic materials are now available which exhibit good high-temperature properties and are reasonably resistant to solvent attack. Second, there has been a mutual adaptation of these materials and advanced composite fabrication methods. This combination has resulted in advanced composite products whose performance and cost are competitive with those made with thermoset matrices.

High-temperature thermoplastics that are being actively considered for use in advanced composites include aromatic polyesters, poly(phenylene ether), polyphenylene sulfide, polysulfone, aromatic polyetherether ketone (PEEK), and polyimides, such as ether --, ester --, or amide – imides. These materials all contain an aromatic backbone, but differ in the way the aryl groups are linked, as indicated in Table 12. Representative properties of these materials are given in Table 11. These materials can be either amorphous or crystalline. In general, crystalline polymers are more resistant to creep and solvents than the amorphous polymers, but are more difficult to process because they are more subject to shrinkage and warpage.

5. Processing and Fabrication Technology

The manufacture of advanced composite components entails the following basic operations:

1) Surrounding the fibers with the matrix material while the latter is in a nonrigid state
2) Arranging the reinforcing fibers in selected patterns and orientations
3) Solidifying the matrix material under constrained conditions that prevent fibers from moving during the solidification of the matrix
4) Integrating the advanced composite material into the finished component or system.

Most advanced composite components are made by laying up precoated fibers. However, the order of the first three steps can be changed, depending on the type of resin system and process technology selected.

Advanced composite components can be manufactured by a variety of fabrication processes. The particular process choice made by a manufacturer depends on both the composition and the structure of the composite materials used to fabricate the part, as well as on the complexity of the design and part. Each step in the forming process is affected by a combination of fiber characteristics, the resin type, and the position in the fabrication process. The orientation process (step 2), if carried out with bare fiber, is dominated by the fiber handling properties such as yarn quality and toughness. If this step is carried out with matrix resin impregnated yarn, resin viscosity can significantly alter the process rate. In the choice of consolidation technology (step 3), resin characteristics such as cure chemistry, resin viscosity, heat transfer, and reaction kinetics will control the process. In the final step of joining the composite section to other components (step 4), the process, while affected by resin type, is primarily application specific.

It is self-evident that different processes are required to fabricate a polymeric matrix composite part and one made with a metallic matrix. In fact, even small differences in the properties of the matrix material significantly influence the choice of processing methods used to fabricate composite components. For this reason, the rest of this chapter is organized by the type of matrix material.

Processing technology choices are also influenced by non-material-product characteristics, such as part geometry, the number of parts required and their rate of production, reliability requirements, the usual economic considerations of the relative costs of capital, labor, and raw materials and the desire to minimize the total costs of producing a part to meet a given set of specifications.

5.1. Thermoset Resin Matrix Composites

5.1.1. Classic Low-Volume Production Methods

Traditional methods of fabrication of advanced composite structures in the aerospace industry have entailed cutting and manual lay-up of preimpregnated tapes of collimated fibers in a prearranged design, which are then cured by the application of heat and pressure to form the desired composite structure.

Combining the Matrix and the Reinforcement. Thermoset "prepreg" (preimpregnated) tape is the basic starting material now used in fabricating most advanced composite structures. These are most commonly unidirectional tapes that contain parallel strands of fibers that are bonded to each other by a thin film of partially cured resin. As indicated in Figure 6 nonwoven unidirectional prepreg tape is made by wetting parallel strands of filaments in a resin tank, passing the impregnated filaments through a set of doctor blades to control the resin content, collimating the filaments on a removable paper substrate, and then driving off the volatiles that are present by passing the tape through controlled-temperature ovens to attain a fiber concentration of 65 vol %. The resulting B stage product is a dry, relatively tack-free material that is relatively easy to handle. There are two categories of prepreg tapes: (1) continuous tapes, generally less than 3 in. (7.5 cm) in width, and (2) "broad goods," which are sheets whose dimensions are measured in meters.

Figure 6. Typical steps in the fabrication of composite tapes a) Creel; b) Surface treatment; c) Resin; d) Backing paper; e) Carrier cloth; f) Removable backing; g) Glass or carbon filaments; h) Resin; i) Glass or carbon yarns

If the fiber can be woven, an alternate form of prepreg is obtained by drawing a woven fabric through the impregnating resin solution. The fiber content of woven prepregs is somewhat

less than that of unidirectional tape, from ca. 55 vol % to 65 vol %, depending on the fabric weave.

The various reinforcing fibers and thermoset resins discussed above have been combined by a number of suppliers to provide composite molders with a wide range of commercially available prepreg materials. While the exact compositions of prepreg materials are proprietary, prepreg suppliers certify their physical and processing properties, and their compliance to military and industry specifications and quality control standards. Specifications include the following:

1) Composition: fiber type and matrix type
2) Content: volatiles content and volume fraction of resin matrix or reinforcement in cured composite
3) Processing characteristics: shelf life as a function of storage temperature, tack (a measure of adhesion of the prepreg), flow (resin flow during curing), and gel time as a function of temperature.

Prepregs are attractive to molders of advanced composite components because they are relatively easy to handle and because their use generally results in cured laminate structures that exhibit reasonably reproducible properties. While these are significant advantages, there are also certain inherent disadvantages associated with thermoset prepregs. These include a very short shelf life (less than 24 h) at ambient conditions, necessitating refrigerated shipment and storage. A second limitation is that each prepreg material on the market is unique and generally not compatible with similar prepregs (i.e., prepregs that result in a composite with similar properties) offered by other suppliers. In general, the unit price of a prepreg is at least equal to the unit price of the contained fiber.

Fiber Orientation. The advantage of using prepreg tapes is the ability to cut them into specific patterns and then arrange the pieces individually to define the internal structure and contours of the composite part. This lay-up method, which is illustrated in Figure 7, is best suited to flat or slightly curved surfaces. More convoluted parts can be layed up by stacking woven prepregs over a suitably shaped preform. This forming method offers the advantages of versatility in selecting fiber orientation and in allowing the incorporation of different types of fiber (e.g., carbon and aramid, or aramid and glass) to achieve an optimized structure. The disadvantages of manual lay-up as a fabrication method are that it is slow, extremely labor intensive, subject to human error, and consequently an expensive operation.

Figure 7. Elements of lay-up forming

Consolidation of the Composite. Consolidation, or curing, of the layed-up prepreg structure is most commonly achieved by the application of heat and pressure, as outlined in Figure 8. As previously noted, during the cure of thermosetting polymers, the molecules react with each other to form a more rigid network of cross-linked molecules. Epoxy matrix composites are cured at temperatures of 250 °F (121 °C) to 350 °F (177 °C), depending on their formulation. High-temperature resins, such as polyimides, require cure temperatures in excess of 500 °F (260 °C). Alternately, curing can be achieved by the application of other energy

sources, such as X-ray, microwave, or dielectric radiation.

Figure 8. General methods of curing

Pressure is also applied to ensure compaction of the fibers and resin and to establish the dimensions of the part. This is most easily achieved by bag molding. In this method, the prepreg lay-up is encased in a flexible airtight sheet or blanket and a vacuum is applied to the material in the bag so that the atmosphere exerts pressure. The pressure differential may be increased by placing the bag in an autoclave. Evacuation is a useful method for reducing or eliminating volatiles prior to or during cure, thereby reducing the formation of voids in the composite structure. Bag molding is used for curing large and complex parts. However, it is a relatively slow process, which may entail the application of pressure to the part for a period of 2 – 4 h, followed by up to a day in a postcure oven.

Matched die compression molding and elastomeric tooling are also commonly used to cure prepreg lay-ups. In compression molding, prepreg is layed up in the cavity of a two-part metal mold. The mold assembly is then placed between the platens of a hydraulic press, and pressure and heat are applied until the resin cures. Elastomeric tooling is a variation of matched metal tooling, which does not require the use of a hydraulic press. In this instance, the prepreg layup is placed in a metal mold with a silicone rubber mandrel. The mold is then bolted shut and placed in an oven. Thermal expansion of the rubber provides the pressure necessary to consolidate the composite. The advantages of these methods over bag molding techniques are that they provide a rigid, predefined envelop for enclosing the composite part and that they result in shorter curing times because of higher heat transfer rates.

System Integration – Joining Methods. Not all functional characteristics required of an advanced composite material can be attained in a molded part. In spite of the fact that it is possible to mold advanced composites into very complex geometrical shapes, it is sometimes necessary to machine a cured composite material or to attach it to another material. Because of the directional characteristics of the mechanical properties of advanced composites and the brittle nature of thermoset resins, proper joint design is critical to prevent stress concentration around joints and premature failure of the assembly. In general, factors of safety used in the design of attachments of advanced composite parts are usually more conservative than those used in metallic designs.

Since thermoset resins cannot be joined by the equivalent of welding or brazing, adhesive bonding is the most commonly used method of forming permanent joints. This method is of limited value if coefficients of thermal expansion of the materials to be joined differ greatly or are dissimilar to that of the adhesive. Advanced composites can be fastened mechanically by drilling holes and joining with rivets, bolts, or pins. The fiber discontinuities caused by machining can be eliminated by molding in suitable inserts.

5.1.2. Automation of Traditional Production Methods

The major disadvantages of the traditional approach to the production of advanced composite structures described above have been its low productivity and high production costs. To overcome these economic disadvantages, while maintaining versatility in selecting fiber orientations and flexibility in terms of being able to produce a variety of composite structures in a given manufacturing facility, the aerospace industry has invested heavily in advanced manufacturing methods, such as robotics and other computer-aided manufacturing tools. Machine tool builders and material handling suppliers have developed a diversity of process automation modules to support the fabrication of composite structures, from the removal of the

prepreg from refrigerated storage to the placement of the composite part on an airframe. These modules include automated, guided vehicles to transfer material from one production site to another, integrated composite cutting centers, automated tape-laying machines, "intelligent" autoclaves which incorporate computer control of the major process parameters, automated on-line inspection methods based on ultrasonic scanning, and more recently on CAT (computer-aided tomography) scanning, and automation of secondary processes such as trimming, drilling, and fastening [55–65].

5.1.3. Alternate Production Methods

Advanced composite structures can also be produced directly from roving and resin. Filament winding and pultrusion are the most important alternate processes. These are continuous or nearly continuous automated processes that are better suited to high-volume production than the manufacturing methods based on hand lay-up of prepregs.

Filament winding is a method of fabricating hollow composite structures that have one or more axes of rotation from fiber roving or tape. As outlined in Figure 9, continuous fibers or rovings are fed from a creel, drawn through a resin bath, and wound under tension over a rotating mandrel in the shape of the finished part. By controlling the rate of rotation of the mandrel and the position of the carriage that deposits the filaments onto the mandrel, layers of reinforcing fibers can be placed in a variety of predetermined patterns over the length of the mandrel. Originally, filament winders were mechanical machines in which the relative motion between the carriage and the mandrel was determined by gearing. With these machines, wind patterns were those that had a constant wind angle and an adjustable dwell (no carriage motion while the mandrel turns). Other limitations of the mechanical machines were the difficult gearing calculations and the often lengthy gearing changes needed to change patterns. A major technological advance was the application of dedicated computer control to filament winding. Motion of the carriage relative to the rotating mandrel is controlled by software, which allows wind patterns to be modified without changing gears. There are many types and forms of filament winders available, including horizontal winders, vertical winders, two-axis winders, four-axis winders, and advanced machines with seven or more axes of controlled direction. Filament winders can be used to wind very large parts. For example, the mandrel of a large filament winding machine may be 4 m (160 in.) in diameter and 11.5 m (460 in.) long, and weigh in excess of 45 000 kg (100 000 lbs) [66].

Figure 9. Elements of winding methods

Because of the need to deposit the filaments under tension and because of the rapid motion of the carriage, the filaments being wound into a composite part need to be somewhat ductile. The process has been used successfully with more ductile fibers such as aramid, high-strength carbon, and glass, which exhibit a strain to failure of 1 % or more. Very brittle high-performance fibers, such as silicon carbide and very high modulus carbon, are not compatible with filament winding.

After the filament is deposited on the mandrel, the resin is then cured either at room temperature or in an oven, depending on the size of the part and the characteristics of the resin matrix. The composite part is then stripped from the mandrel.

Pultrusion is a method of producing continuous reinforced composites of constant cross-section, as outlined in Figure 10. In pultrusion, continuous filaments are drawn through a resin bath for impregnation and then pulled through a hardened steel die. The die orients the reinforcement, sets the final shape of the laminate, and controls its resin content. Cure may be completed within the die or may require additional heating after the formed composite leaves the die. Many structural shapes such as I-beams, channels, solid rods and bars, hollow rectangular beams, and flat plates can be pultruded.

Some manufacturers have used postforming of partially cured pultruded stock to produce pultrusions of variable cross-section.

Figure 10. Pultrusion – an illustration of continuous forming and curing

5.2. Thermoplastic Resin Matrix Composites

The various production methods used to manufacture thermoset resin matrix composites are also applicable, with certain modifications, to the production of thermoplastic resin matrix composites. The key difference in the processing of these two classes of materials is in the applied time – temperature profile. Although long periods of time at elevated temperatures are required to cure properly thermosetting resin matrix composites, consolidation of thermopastic resin composites is achieved by heating to the fusion temperature of the resin and then cooling rapidly. The use of thermoplastic resin matrices eliminates the cure time delays that can stretch into days for large thermoset parts. Because of the resultant short cycle time, mass production applications of advanced composites are being enabled by the use of thermoplastic matrix materials. Other inherent manufacturing advantages of thermoplastic resin composites are that the raw materials have an inherently long storage life at room temperature, that molded parts can be postformed, and that scrap parts can be reclaimed.

Tape lay-up, filament winding and pultrusion are all adaptable to the production of thermoplastic resin matrix composites. A variety of uniform thermoplastic resin – fiber prepregs is available from commercial sources. Developmental products include tapes of glass, aramid, carbon, or other reinforcing fibers, which are combined with engineering thermoplastics such as polyetheretherketones, polyphenylene sulfide, polyamides, or thermoplastic polyester, as well as lower cost thermoplastic materials such as polypropylene, polyethylene, and ABS. These prepregs are made by a variety of processes, which include pulling the reinforcing fiber through a molten resin bath and a forming die, interweaving the reinforcing fiber with a thermoplastic monofilament of equal diameter, impregnating the reinforcement with minute particles of resin in a fluidized bed, or coextruding resin-sheathed fibers. It is also claimed that thermoplastic resin prepregs are better adapted to automatic tape laying systems than thermoset prepregs because of their lack of tack at ambient. Once the tapes are layed up, as with thermoset resin matrix composites, a thermoplastic resin matrix composite part can then be consolidated, if needed, by bag molding or compression molding, with the appropriate modifications of the time – temperature profile as mentioned above.

Thermoplastic filament winding systems are not radically different from thermosetting resin filament winding systems. The major difference is in providing means of preheating resin-coated rovings to the resin melt temperature prior to their being deposited on the mandrel. By heat loss to the surroundings the resin is resolidified and the composite structure is consolidated once the filaments are laid down. Heat sources that can be used range from ultrasonics and infrared for low-temperature materials to focused plasma guns and laser beams for high-melting engineering thermoplastic matrices.

The major difference between pultrusion systems for thermoplastic resin matrix composite materials and thermoset matrix composites is in the temperature of the resin impregnation bath and pultrusion die. Thermoplastic pultrusions are made by drawing filaments through a hot bath of molten resin and then through a chilled die, which shapes and cools the material to its final form.

5.3. Design Integration [67], [68]

The complexities of these materials force a different approach to design. The traditional design approach to any complex system was to treat it as an assemblage of relatively isolated systems to minimize interdependencies. The lim-

itations of the "open loop" process have been recognized, and a significant change is taking place. The emphasis is shifting to "configuration integration," by which technological advances, new products, or system requirements are permitted to impact the total configuration. Capabilities and advances in diverse disciplines can be coupled to achieve the valuable benefits of a multidisciplinary interaction and the full potential of these anisotropic materials. Thus, groups of independent specialists are being replaced by multidisciplinary teams.

The part performance depends not only on the geometric envelope, but also on the fiber orientation. In this way the material properties can be treated as a design parameter that can be varied to best meet the overall system requirements. The reduction to practice is best realized through the development of computer-aided design (CAD) systems that allow these very complex calculations to be made. This can then be coupled with a computer-aided manufacturing program that allows a process such as filament winding and tape lay down to be directly controlled by the design. The result is both an improved efficiency in the use of the materials and an efficient composite manufacturing process limited only by the limits of the available hardware.

6. Properties of Advanced Composite Materials

The design of load-bearing structures requires knowledge of a large number of material properties. Resistance to deformation is characterized by the stiffness of the material as described by Young's moduli, shear moduli, and Poisson's ratio. The ability to support loads is described by the tensile or compressive strength. Coefficients of thermal expansion characterize changes in dimensions under thermal loads.

The properties of the polymeric components of composite materials are dependent on the duration, rate, and frequency of applied loads or deformations. This viscoelastic behavior is translated into the response characteristics of the composite and is manifested as creep, stress relaxation, and energy dissipation, which may result in internal heating. Metals and ceramics may also exhibit such behavior near the melting point; however, at normal operating temperature, these effects are negligible and are not usually included in traditional design considerations. If the viscoelastic behavior of polymer composites is ignored, the consequences may be disastrous. Consequently, mechanical properties should be characterized as functions of time, frequency, and temperature. The dependence of polymer composites on time, frequency, and rate of loading is reflected in quantities such as fatigue life, fracture toughness, and impact strength.

In addition to mechanical requirements, composite materials may be employed in applications involving the shielding of electric or magnetic fields, electrical and heat conduction, and permeation by fluids or gases. These characteristics are described by the appropriate transport properties: dielectric constant, magnetic permeability, thermal conductivity, electrical resistivity, and diffusion coefficient.

All of the above properties may be modified by environmental effects such as infrared and ultraviolet radiation, moisture, etc.

6.1. Properties of Composite Structures

A unique feature of composite materials is the directional dependence (or anisotropy) of the various properties. The feature is intuitively clear for a unidirectional lamina; i.e., properties along the direction of the fiber reflect the higher performance characteristics of the fiber while properties perpendicular to the fiber tend toward the behavior of the matrix material. This directional dependence of the properties introduces the opportunity to further tailor the material to specific applications. The alignment of stiff and strong fibers along anticipated load paths can yield highly efficient structures.

The most common method of controlling fiber directions is shown in Figure 11. In this manual lay-up procedure, sheets of continuous fiber prepregs can be stacked in a variety of prescribed orientations. The effects of fiber orientation, developed through different stacking sequences, are illustrated in Table 13. Properties of aluminum and cold rolled steel are included for comparison.

Table 13. Effect of fiber orientation on mechanical properties of various fiber reinforced composites [69]

Figure 11. Representative composite lay-up configurations

To compensate for the low transverse properties of unidirectional material (0 °), laminates of unidirectional fiber may be cross-plied at right angles to each other (0, 90°). The resulting structure has improved transverse properties compared to the unidirectional structure, but poorer longitudinal properties. Furthermore, the in-plane shear strength is not significantly improved over that of the unidirectional structure. Shear strength can be improved, but at the expense of longitudinal and transverse properties, by a stacking sequence of ± 45 °. A stacking sequence of 0 °, 45 °, and 90 ° plies (also illustrated in Fig. 11) yields a quasi-isotropic structure in which the in-plane properties are independent of direction.

As shown in Table 13, woven fabric structures are similar to crossplied laminate structures; however, they are usually less stiff and strong due to the various weaving patterns. Fabric geometries offer the advantage of drapability and handling characteristics that facilitate the fabrication of geometrically complex shapes.

The structures described in Table 13 consist of a single-fiber component. However, the material properties may be further altered through hybrid composites consisting of two (or more) types of fibers in a common matrix. By judicious positioning of different fibers, it is possible to greatly expand the range of properties that can be achieved with composite materials systems [70].

The benefits of tailoring materials through control of composition and reinforcing geometry greatly complicate the direct characterization of the properties of composite structures. For homogeneous materials, such as aluminum and steel, it is feasible to develop testing programs to generate design data concerning stiffness, strength, fracture toughness, etc. In contrast, the properties of a composite structure are strongly dependent on the composition and the reinforcing geometries associated with the various methods of fabrication. The labor and expense required to acquire direct characterization data for the directionally dependent properties for each variation in composition and geometry prohibit the use of this traditional approach. Consequently, analytical techniques that predict behavior in terms of composition and reinforcing geometry have emerged as an impor-

Figure 12. Effect of environment on flexure strength of unidirectional graphite reinforced composites

tant component of the technology of composite materials. These analyses proceed at two levels, laminate analysis and micromechanics, as further discussed below.

6.2. Laminate Analysis

In this treatment, as in manufacturing, the unidirectional lamina is taken as the basic structural element. The microstructure of the individual plies is ignored and each ply is treated as a homogeneous material with different properties along and perpendicular to the fiber direction. Building on techniques inherited from plywood, tires, and cloth reinforced plastics, analysts have constructed sophisticated techniques for defining the optimum orientation of plies for specific applications.

Laminate Theory. The starting point for laminate analysis is a knowledge of the properties of a unidirectional ply. The ply is treated as a homogeneous orthotropic material with different properties along and perpendicular to the fiber direction. The direction-dependent properties are formulated as matrix arrays according to the methods of anisotropic elasticity theory (an introduction to anisotropic elasticity is given in [71]). The structural member is considered to consist of variously oriented orthotropic plies, the boundary conditions on the structural member are formulated, and laminated plate (or laminated shell) theory is used to determine stresses on individual plies. Relative orientations of the plies, which best match the properties of the plies to the loading conditions imposed on the structural member, are determined.

The execution of laminate analysis requires mathematical treatments beyond the scope of this review. An introduction to laminate analysis is given in [72]. An important result of laminate analysis shows that a structure made from a sufficient number of plies stacked in the sequence illustrated in Figure 11 approaches the behavior of a quasi-isotropic material. For this structure, the in-plane properties are independent of direction. For example, the in-plane Young's modulus (E_0) is uniform and is related to the longitudinal modulus (E_L) and transverse modulus (E_r) of the ply through the following relationship: $E_0 = (3/8)\,E_L + (5/8)\,E_r$. Tsai [73] recommends that comparisons between different compositions of composite materials should be made in terms of these properties rather than the common practice of comparing longitudinal properties and ignoring the possibility that the transverse properties might not be acceptable.

Figure 13. Effect of matrix material on interlaminar shear strength of *p*-aramid reinforced composites
1 ksi = 6.895 × 10^6 Pa

Typical Properties of Unidirectional Laminae. The application of laminate analysis requires a complete set of properties for the individual lamina. Some properties of representative, unidirectional materials are presented in Tables 14, 15, 16, 17, 18, 19. The influence of various reinforcing fibers on the room-temperature properties of otherwise comparable epoxy matrix composites is illustrated in Table 14. Conversely, the effects of various matrix materials for comparable groups of carbon fiber and *p*-aramid fiber reinforced composites are shown in Tables 15 and 17, respectively, as well as in Figures 12 and 13. The impact of various matrix materials on selected properties of carbon fiber reinforced composites is illustrated in Table 18. Tables 16 and 19 provide data on the effects of temperature and humidity on *p*-aramid and glass composites in epoxy matrix resins.

Although the utilization of laminate analyses reduces the characterization effort by focusing attention on the characterization of unidirectional specimens, the wide range of possible compositions and effects illustrated in Tables 14, 15, 17, 18 tends to preclude a total reliance on direct laboratory characterizations.

6.3. Micromechanical Models

Starting ca. 1960, emphasis was given to predicting the properties of the individual unidirectional plies in terms of the properties and concentration of the fiber and matrix components. These models became a necessary supplement to laminate analysis as the choices of components became sufficiently numerous to make a strictly empirical approach economically impractical. In this approach, the inhomogeneous nature of the ply at a microscopic level is recognized. Various models have been developed by introducing approximations concerning the packing geome-

try and/or the response fields within the ply. By these models the mathematical analyses can be performed to relate the properties and concentrations of the fibers and matrix to the effective properties of the ply.

A detailed treatment of the various micromechanical models is beyond the scope and intent of this review. Introductory treatments are given in [74–76]; more advanced treatments are given in [77] and [78].

For the purposes of model development properties may be grouped under the classifications of averaged or localized properties. The class of properties within the first group can be treated in terms of average properties and average response characteristics. Thermoelastic properties, certain viscoelastic properties, and transport properties fall within this group. The class of the properties belonging to the localized group is strongly dependent on the statistical features of the material properties as well as fluctuations in microstructure; thus, properties belonging to this group are much more sensitive to the nature of the local environment. Properties such as tensile strength, fatigue life, and fracture toughness fall in this group. For such properties, the identification of modes of local failure (i.e., the weak links) is a prerequisite to the application of model relationships.

Averaged (Effective) Properties. Numerous important properties of advanced composites can be predicted by micromechanical models. They include thermoelastic properties such as Young's modulus, Poisson's ratio, shear modulus, and the thermal coefficient of expansion; transport properties such as magnetic permeability, electrical conductivity, thermal conductivity, and diffusion coefficients; as well as expansional strains induced by environmental factors such as moisture adsorption.

All of the above properties share the common feature that they can be treated in terms of average properties and the overall (average) response for the composite system. In principle, the average thermoelastic and transport properties of a ply can be obtained by specifying (1) the details of the geometry (fiber shape, packing

∗ 2-Week exposure at 71 °C and 95 % relative humidity

geometry, and spacing), (2) the distribution of the thermal, mechanical, or electrical loads on the surfaces of the ply, and (3) the connectivity between the fiber and the matrix phase. The average bulk response can be determined by taking the appropriate volume averages, thereby relating the volume fraction of the components and their properties to the average properties of the ply.

The simplest models for predicting thermoelastic and transport properties may be developed intuitively by treating response to mechanical, thermal, and electrical loads by analogy to springs (for mechanical loads and thermal expansion) or resistors (for thermal or electrical transport), which can be arranged either in parallel or in series. The analogies are illustrated in Figure 14.

The longitudinal response characteristics are treated as if the components of the ply react to the loads by parallel response. For mechanical loads, the central feature of this analogy is the assumption that each component is subject to the same strain. This analogy yields the following simple linear relationship:

$$P = \sum_{i=1}^{n} v_i P_i \tag{8}$$

where P_i is any one of the pertinent longitudinal mechanical, thermal, or transport properties of the ith component. The concentration terms, v_i, are the volume fractions of the ith component given by

$$v_i = V_i / V \tag{9}$$

where V_i is the overall volume of the ith component and V is the total volume of the ply. The volume fractions must satisfy the following relationship:

$$\sum_{i=1}^{n} v_i = 1 \tag{10}$$

The transverse response of the ply to mechanical and other loads is modeled by considering that the components react to these loads as though they were connected in series. The central feature of this analogy (for mechanical loads) is the assumption that each component is subject to

the same stress. This analogy yields the following simple reciprocal relationship:

$$\frac{1}{P}=\sum_{i=1}^{n}\frac{v_i}{P_i} \tag{11}$$

Table 19. Air aging of *p*-aramid unidirectional epoxy composites * at 150 °C

Hours exposure at 150 °C	Tensile strength (in MPa) ** at composite thickness		
	14 mils	42 mils	73 mils
0	1234	1207	1289

2000	1110	1138	1241
8760 (1 year)			1082
19600	676	883	

* SP-306 Epoxy, 50 vol % fiber;
** Measured at room temperature after exposure

For a two-component ($n=2$) fiber–resin composite, Eq. (10) becomes

$$v_f+v_r=1$$
or
$$v_r=1-v_f$$

and Eqs. (8) and (11) can be expressed as follows:

$$P=v_f P_f+v_r P_r$$
and
$$1/P=v_f/P_f+v_r/P_r$$

If the property of the fiber (P_f) is considerably greater than the corresponding property of the matrix (P_r), these equations are reduced to the following:

$$P\approx v_f P_f$$

for longitudinal properties and

$$P\approx P_r/v_r$$

for transverse properties. These simple relationships, which have become popularly known as the "Rule of Mixtures," indicate that for advanced composite materials in which fiber properties are considerably greater than matrix properties, the longitudinal properties of a ply are dominated by the fiber contributions and the transverse properties are dominated by the contributions of the matrix.

Figure 14. Simple composite models

While it has been demonstrated that the Rule of Mixtures relationship for longitudinal properties gives excellent agreement between the predicted and observed properties of continuous fiber composites, prediction of transverse properties is usually underestimated. Considerable effort has been devoted to developing more accurate and comprehensive models and methods of analysis. Improved models for predicting shear moduli and transverse properties are discussed in [72–77].

Strength of Composites (Localized Properties). In contrast to the thermoelastic properties, an understanding of the average response fields is insufficient for a description of strength. The strength of a system is dependent on the behavior at local levels, with the weaker sections of the material exerting more influence than the strong sections. Because of this weighting of the weak elements, the strength of the assembly is less than the average strength of the individual components. The appropriate weighting of the weak elements is dependent on the mechanism or mode of failure.

The weak elements or flaws can be due to characteristics either of the fibers or of the matrix. Even in the case of longitudinal ten-

sile strength, while the direct contribution of the strength of the matrix phase to the tensile strength of the composite is negligible, an improper choice for the matrix phase could seriously detract from the realization of the full strength potential of the reinforcing fibers.

The tensile, compressive, and shear strengths of a composite are determined by a complex interplay between several factors:

1) The mechanical properties of the fiber system, taking into account the statistical distribution in the tensile and/or compressive strengths of individual fibers
2) Statistical variations in the fiber – resin geometry in a ply
3) Coupling between the fiber and the resin phase, taking into account not only the bond strength at the fiber/resin interface, but also stresses induced by the difference in the responses of the fiber and resin to environmental changes; for example, a mismatch in the coefficients of thermal expansion of the fiber and resin phases can cause strains to develop near the fiber – resin interface when the composite is subjected to significant changes in temperature, as often occurs in the composite manufacturing process.
4) The viscoelastic properties of the resin phase, taking into account possible spatial variations in these properties due to presence of the fibers; one of the unique features of composite materials is the extremely large surface area over which interfacial contact is made. Because of the large surface : volume ratio and the heterogeneous nature of the matrix resins, particularly the multicomponent thermosets and semicrystalline thermoplastics, the probability is high that certain components of the resin phase are preferentially adsorbed on the fiber surface, thus resulting in spatial variations in both the composition and the properties of the matrix phase.
5) Flaws and discontinuities in the matrix phase.

In summary, the strength of a composite is determined by a complex interplay between all of the above factors; the achievement of the full capabilities potentially available from high-performance reinforcing fibers requires careful control over the extent to which each of the above factors exerts its influence. Theoretical models can offer only qualitative guidelines as to their relative significance [70–77].

7. Applications

Historically, advanced composite materials have been used for reasons of performance in applications where their value in use is the driving economic consideration. The major impetus has been their potential for reducing the mass of a structure due to their high specific stiffness and specific strength. More recently, however, the focus has shifted to the need for cost reduction through parts consolidation and total part count reduction.

Advanced composite materials have found greatest use in applications where mass savings result in significantly improved performance, thereby allowing the product to be value priced. This criterion applies to high-performance military aircraft, where lower mass translates into higher speed, greater acceleration, and/or greater payload, which are the essential elements of survival, much less victory in combat. It also applies to wide classes of equipment that use human muscle power as the motive force. Better control and ease of handling, and thus improved performance, have been the driving factors behind the use of advanced composites in sports equipment or medical prostheses.

Advanced composite materials are also being used in applications where mass reduction results in significantly lower life cycle costs. This criterion applies broadly to all forms of transportation equipment, where reduced system mass results in directly increased payload or reduced fuel consumption.

Missiles and rockets are extreme examples of transportation vehicles in which any small reduction in mass is extremely valuable. For example, the Space Shuttle System weighed 1.9×10^6 kg at liftoff. This was many times larger than the weight of the Orbiter, which was 68 000 kg, or of its low earth orbit altitude payload of ca. 30 000 kg [83]. On the basis of the cost of a Space Shuttle launch of ca. \$ 80×10^6, it cost ca. \$ 2700/kg to send an object into low earth orbit. Sending an object into geosynchronous orbit is even more constrained in terms of maximum payload, ca. 2000 kg, and costs, which range from ca. \$ 20 000 to \$ 60 000/kg.

Table 20. Reduction in lifetime fuel consumption per pound of mass savings for various modes of transportation

Mode of transport	Nominal gross mass, kg	Nominal life of equipment, km of use	Liters per km and kg of mass	Lifetime fuel reduction per kg of mass saved, L
Aircraft				
Light pleasure craft	1 400	3×10^5	1.3×10^{-4}	39
Business jet	5 500	3×10^6	1.4×10^{-4}	420
Commercial transport	95 000	3×10^7	8×10^{-5}	2 400
Turbine helicopter	1 400	1×10^6	3.3×10^{-4}	330
Automotive vehicles				
Passenger auto, gasoline	1 400	2×10^5	7.0×10^{-5}	14
Passenger auto, diesel	1 400	2×10^5	5.0×10^{-5}	10
Intercity bus	16 000	2×10^6	1.0×10^{-5}	20
Commercial truck	27 000	2×10^6	7.0×10^{-6}	14

The effects of mass reduction on the fuel consumption of various common modes of transportation are summarized in Table 20. The data presented in this table are based on published fuel consumption and vehicle utilization data. An economic value of mass savings for vehicles used to serve these various modes of transportation is obtained by assigning a net present value to the fuel that otherwise would have been consumed. Not surprisingly, mass reduction has greater value in aircraft, particularly commercial transport aircraft, than it does in ground transportation equipment.

The value of providing tailored anisotropic material properties for reasons other than mass savings is now also being recognized and is being applied in developmental aircraft, as discussed further below. Other general technical characteristics of advanced composite materials that have led to their use include corrosion resistance and their relatively high transparency to electromagnetic radiation.

In some instances, use of an advanced composite has been based on the unique characteristics of a specific fiber – matrix combination in addition to the general characteristics described above. In some applications, advanced composites reinforced with carbon fibers are used specifically because of (1) the high electrical and thermal conductivity of these fibers or (2) their unique thermal expansion characteristics, which makes these composites the materials of choice for constructing low-mass structures that do not distort under thermal gradients, such as telescope reflectors and antennae. Conversely, glass or *p*-aramid fiber reinforced composites are used in applications, such as radomes, that must be transparent to electromagnetic radiation and, thus, require a material with a low dielectric constant.

Advanced composite materials are now also used for reasons of cost as well as performance, as in the case of helicopter fuselages. In these applications, complex structures, normally made from a large number of metal parts, are now being fabricated from advanced composite materials as a single, integrated component. Cost savings derive from the smaller number of parts required and the lower assembly costs.

In the concluding sections of this chapter, a select number of representative applications of various composite materials are presented. These examples are chosen to illustrate various materials, manufacturing processes, or reasons for using advanced composites. They are not meant to be representative of all possible applications of advanced composite materials.

Satellite Systems. Satellite systems are now commonly utilized to perform a wide variety of military and civilian purposes. Commercial satellites are used for telecommunications and TV broadcasting. Government satellites are used to gather data for weather forecasting and geophysical studies, to conduct a variety of scientific experiments, and to perform a variety of military missions.

The generic technology issues and specific materials and structures criteria that address these issues are as follows [84]:

- Good dimension stability by low thermal expansion, high thermal conductivity, and no outgassing
- High structural rigidity (specific stiffness) by high modulus and low density
- Noncontaminating by no outgassing

- Rapid track and point capability by good vibrational damping characteristics
- Deployable/erectable in space by low mass (shuttle transportable) and joining and fastening capabilities
- Survivable in laser/nuclear natural environments by high strength, no induced outgassing, high-temperature integrity, controllable reflectivity, and good temperature dissipation control
- Minimal space charging by good electrical conductivity.

The specific criteria include minimum mass, low thermal distortions, well-separated natural frequencies, high damping, environmental stability, as well as good electrical conductivity and a low thermal coefficient of expansion. Carbon fiber reinforced composites with their high specific strength and specific stiffness, their conductivity, and their controlled coefficient of thermal expansion that approaches zero (or even a negative value, depending on their structure), have become the materials of choice for satellite structures.

Military Aircraft. The United States Department of Defense has supported the development and use of advanced composite materials since the early 1960s. Use of advanced composite materials has increased with each new type of aircraft. Use of advanced composite materials has progressed from replacement of metal in a few selected secondary structures, whose failure in flight would not endanger the aircraft, to designs in which advanced composites are used in primary structures critical to airworthiness and safety, and account for over 20 % of the mass of the airframe.

The first production part made of an advanced composite to reach flight status, in 1970, was a boron – epoxy horizontal stabilizer on the Grumman/U.S. Navy F-14. This 85-kg part, which is still in service, represents only 0.8 % of the structural mass of this airplane. In contrast, the McDonnell-Douglas/U.S. Navy AV-8B Advanced Harrier VSTOL aircraft contains over 450 kg of advanced composites, which is ca. 20 % of its structural mass. Major components made from carbon – epoxy composites include the forward fuselage, as well as wing substructures, such as spars, ribs, and skins, which account for over 70 % of the wing mass.

By the mid-1990s, it is anticipated that advanced performance military aircraft must be capable of maintaining supersonic flight for long missions without refueling and at the same time demonstrate superior agility, VSTOL capability, and superior firepower (e.g., high payload). To meet these requirements, aircraft size and mass will be severely constrained, and advanced composites will be extensively used. For example, not only will proposed United State Air Force Advanced Tactical Fighter (ATF) have a structure made largely (40 – 60 %) of advanced composites and, thus, weigh 25 % less than a comparable one made of aluminum or titanium, but also the total configuration of the aircraft will be influenced by advanced composite materials.

The ATF could have a forward-swept wing, which would be aerodynamically more efficient than the traditional rear-swept wing. Advantages of forward-swept wings are reduced drag, improved control, and greater resistance to spin leading to smaller engines and lighter, less costly aircraft. Despite its advantages, the forward-swept wing has been sparingly employed because the phenomenon of divergence makes it a structurally unstable design, as discussed in more detail in [85]. Conventional metallic structures of sufficient strength and stiffness to counter these divergence effects at desirable sweep angles are also very heavy, and result in unacceptable mass penalties.

The problems of divergence can be overcome by using advanced composite materials without incurring a major structural mass penalty. Since laminates can be fabricated with fiber directions selected to produce a wide variety of twisting characteristics, wing skins can be tailored to twist the leading edge down while bending, so that the wing is then structurally stable.

Radomes. Glass – epoxy and, more recently, *p*-aramid – epoxy composites are extensively used in radomes for both military and civilian aircraft. The combination of low mass, damage tolerance, and low dielectric constant (needed for signal transparency) uniquely qualifies these composites as the materials of choice.

Helicopters. Since the introduction of the first production helicopters, damage caused by fatigue of critical flight structures has had an

adverse effect on all aspects of rotorcraft operations. Thus, helicopter designers have been interested in using advanced composite materials since their commercialization, and the current designs of all major manufacturers of rotorcraft make extensive use of advanced composites for reasons of cost as well as performance.

The CH 53-E Blackhawk developed by Sikorsky for the U.S. Army was the first military helicopter to make extensive use of advanced composites. This rotorcraft contains ca. 350 kg of advanced composites, mainly *p*-aramid – epoxy composite. *p*-Aramid composites are also extensively used on the Boeing CH-47 Chinook helicopter and on the Hughes AAH-64A close ground support helicopter. The high impact resistance and toughness of *p*-aramid fibers led to these composites being preferred over carbon fiber reinforced composites, as well as over aluminum, for military helicopter structures. These properties result in a rotorcraft that is much less sensitive to damage from exploding shells and shrapnel.

Helicopter manufacturers are using the technology developed for military programs on the latest generation of commercial helicopters. For example, both the Sikorsky S-76 and the Boeing Commercial Chinook make extensive use of *p*-aramid – epoxy composites. By using *p*-aramid – epoxy composites, the frame of the S-76 weighs 30 % less than that of a structurally equivalent aluminum frame, resulting in a 20 % improvement in efficiency.

The U.S. Army has further pursued the advancement of using composites by supporting the development of the all-composite helicopter (ACAP). The Sikorsky ACAP candidate, designated the S-75, has met or exceeded all the objective and goals that the Army had set for the ACAP program. These included a mass reduction of 22 %, a cost savings of 17 %, and improved crashworthiness, survivability, reliability, and maintainability. The primary materials of construction on the S-75 are carbon and aramid reinforced epoxy.

In addition to a significant mass reduction, one of the major benefits of using advanced composites instead of metals was a sizable reduction in manufacturing costs. Previously complex metal assemblies can now be fabricated as a single, integrated composite part.

Commercial Transport Aircraft. In the past decade, the average price of aviation fuel has increased by an order of magnitude, from 10 ¢/gal to >$ 1/gal. As a result of this escalation, fuel costs have become a dominant cost factor and can now account for 60 % of the direct costs of operating a commercial transport jet. Since a marginal kilogram represents an additional consumption of 600 gal (2400 L) of fuel over the life of the aircraft (see Table 20), a strong economic incentive exists for developing more fuel-efficient transport aircraft. Technical advances that have led to more fuel-efficient transport aircraft have included improved propulsion systems, aerodynamically more efficient designs, and improved structural materials, particularly advanced composites.

Lockheed set the pace in the early 1970s by adapting 2500 lb (1140 kg) of *p*-aramid – epoxy composites on the secondary exterior structures of their L-1011-500 transport. This resulted in a structural mass reduction of 805 lb (366 kg), which contributed to the extended range of this model.

The current generation of commercial transport aircraft, such as the new Boeing 757 and 767 and the Airbus A-310, long-range, wide-bodied aircraft, makes somewhat more extensive use of advanced composite materials. In these aircraft, advanced composites are used in a variety of interior and secondary exterior structures and account for < 5 % of the structural mass. Typical applications include fairing, flaps, and parts of the empennage structure.

It is anticipated that the next generation of commercial transport aircraft will make more extensive use of advanced composites, and that these applications will include important primary structures, such as the horizontal tail plane and elevator, the fin box, and the flaps, in addition to the components already in use. Such increased use is predicated on statisfactory performance of the secondary components that are currently flying and on the development of lower cost, more damage-tolerant composite structures than the epoxy matrix materials now in use.

General Aviation. Some of the most innovative concepts for the integrated use of advanced composite materials have been developed by manufacturers of fixed-wing aircraft for

general aviation. Their incentive is to build a relatively inexpensive (ca. $\$ 1 \times 10^6$), fuel-efficient (>10 mpg), 6 – 10-passenger aircraft capable of transcontinental flight.

The Lear Fan 2100 is the first fixed-wing aircraft to make intensive use of advanced composites. This airplane has an all-composite primary structure that makes extensive use of graphite – epoxy composite materials. This aircraft is currently undergoing testing and evaluation by the FAA and is likely to be the first all-composite airplane to be certified.

The Avtec 400 represents a more radical design approach that is enabled by the use of advanced composites. This aircraft, which is currently undergoing development, uses a canard concept to improve lift and reduce drag. The skins are made of aramid – epoxy for damage tolerance, while carbon – epoxy is used in the spars and other parts that require maximum stiffness and compressive strength.

Another business aircraft of unusual design that makes extensive use of carbon – epoxy composites is the Beech Starship. This airplane has a forward wing that adjusts forward for takeoff and landing and back for flight. Beech is considering a filament wound structure.

Finally, a very special part of general aviation, human-powered flight, owes its realization to advanced composite materials. Without the availability of advanced composite materials, an aircraft light enough to be effectively powered by a human being simply could not have been built.

Ballistic Protection. *p*-Aramid-reinforced composites are being increasingly used in military helmets, for fragment protection on ships, and for military shelters. They are replacing fiberglass and metals in mass-critical applications [89]. The ability of *p*-aramid fabrics to stop high-speed objects is controlled by their dynamic energy-absorbing properties, primarily high tensile strength and specific modulus, complemented by good thermal resistance and high fracture toughness. Special woven fabrics need to be designed to balance positive and negative aspects of fabric cross-overs. Cross-overs help spread the impact by involving more yarns, but in excess, can reduce fabric deflection causing fiber shearing and loss in performance.

Automotive Transportation. Advanced composite materials have been accepted for primary body structures and chassis parts in speciality and racing vehicles, in which light mass and performance take precedence over cost. Their use in production automobiles, however, has been extremely limited for reasons of both high materials costs and lack of a suitable technology for mass production of composite parts and components. The most notable automotive application of advanced composites to date has been the continuous glass – epoxy composite transverse rear leaf spring on the Chevrolet Corvette. This single leaf spring, which weighs only 8 lb (3.6 kg), has a fatigue life that is an order of magnitude greater than that of the much heavier (45 lb, 22 kg) multileaf steel spring that it replaced [90].

This situation may change radically within the next decade because of recent developments in process and materials technology. Computer-controlled filament winding of thermoplastic matrix composites has generated major interest in the automobile industry as a means of producing large intricate parts, such as the frame, the suspension system, and the steering column. In particular, it has been reported that filament wound structural frames for cars with plastic bodies are currently under development by General Motors [91].

There is also active interest in the application of advanced composite materials to automotive engine parts. Prime candidates are those highly stressed parts that oscillate or rotate. High-speed reciprocating parts such as wrist pins, connecting rods, and valve lifters made from advanced composite materials would weigh significantly less than the metallic components now used, and their use would significantly improve engine performance, in terms of vibration, noise, and fuel efficiency.

General Industries/Electronics. While general use of advanced composite materials in the industrial sector on the basis of their mechanical properties has been limited to selected high-speed rotating or reciprocating parts, such as textile machinery components as picking sticks, use of advanced composite materials is increasing in applications that require tailored electromagnetic properties as well as superior mechanical properties. For example, X-ray ta-

bles are currently made of advanced composites because of the combination of stiffness and X-ray transparency. As the electronic industry moves to direct surface mounting of chip carriers, the ability to match the coefficients of expansion of the board and of the chip carrier, coupled with the desired electrical properties, make *p*-aramid reinforced composites attractive materials of construction for circuit boards.

Sporting Goods. The sporting goods and recreational equipment markets were the first significant commercial uses of advanced composite materials. Advanced composites have been successfully used in applications such as golf club shafts, fishing rods, tennis (and other) racquets, archery equipment, hand gliders, windsurfer boards and masts, etc. The successful penetration of advanced composites in these applications is based on psychological as well as technical reasons. While use of advanced composite materials does result in lighter mass and more responsive equipment that can marginally improve performance during play, the ego gratification that comes from using the most expensive, as well as the most technologically innovative, equipment available cannot be discounted in these markets.

Prospective Developments. In less than 30 years, advanced composite materials have evolved from their experimental beginnings to become well-established speciality products used in a wide variety of high-performance applications, where mass savings has a substantial value in use. Since a higher level of complexity is inherently needed to understand and properly use advanced composites than is needed with traditional materials, the successful development of this technology was greatly enabled by changes in the design environment brought about by the dramatic increases in computing power and computerized methods of analysis, design, and control that also occurred during this period.

The value of using advanced composite materials for reasons other than mass savings are now being recognized. These reasons include:

1) The ability to provide tailored anisotropic properties, which allows otherwise unfeasible structural design concepts to be realized by providing an additional degree of freedom in material properties
2) The ability to manufacture complex structures previously manufactured as assemblies of numerous metal parts as single, integrated components of advanced composite materials, which may result in a simpler and less expensive overall manufacturing process

Areas of future advanced composites research include the development of materials that can result in higher performance composites, as well as those that will allow advanced composites to be used more economically.

In terms of improved performance, the emphasis will be on developing composites that exhibit:

1) Superior mechanical properties at elevated temperatures
2) Improved three-dimensional properties
3) Improved toughness and ductility.

Penetration of advanced composite materials into mass production applications, in which their value in use would be modest, will depend on the development of suitable manufacturing processes, as well as lower cost materials. The most significant development in this regard may well be the filament winding of composites of high-strain fiber in a thermoplastic matrix.

1. History

Egyptian records describe the art of confectionery over 3000 years ago. Excavations of Herculaneum, buried under volcanic dust in A.D. 79, revealed a confectioner's workshop. The sweets of those ancient times were often based on honey, but sugar cane juices, boiled to concentrate, were also used in China and India.

The cultivation of sugar cane increased during the Middle Ages. Sugar refining was developed in Persia in the seventh century, and the growing of cane spread through southern Europe to the West Indies and, eventually, to most tropical and subtropical parts of the world. Sugar is also obtained from beet, and production from this source was accelerated in Europe by the Napoleonic Wars and by World Wars I and II.

At the same time, a search for alternative sweeteners led to the development of products from corn and other starches. These now constitute an integral part of confectionery formulations, and their production is a major industry [1–4].

2. Raw Materials

2.1. Physical and Chemical Properties

The properties of the raw materials determine the nature of the confection, its quality, and its shelf life. These include the solubility of sugars and the viscosity of their solutions, the melting points and stability of fats, and gelatinization by colloidal materials such as starch and pectin. The deterioration of sugar confectionery is in most cases due to uptake or loss of water. The reaction of milk products with sugars during cooking processes is an important factor (Maillard reaction). Microbiological activity arising from ingredients used or from external sources must be controlled to avoid spoilage.

2.2. Sweetening Ingredients

Sugar. The main sweetening substance of confectionery is sucrose. This sugar may be of cane or beet origin, and the modern commercial product has such a high degree of purity

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a07_411

(> 99.9 %) that its origin cannot be recognized. In addition, partially refined sugars play a useful part in the flavoring of confectionery. These are variously described as brown sugar, Demerara, molasses, and golden syrup. All are derived from cane sugar because the equivalent products derived from beet have unsatisfactory flavors (→ Sugar).

Invert Sugar. Invert sugar, a product of cane or beet sugar, is made by hydrolysis with acid or enzyme. Sucrose is a disaccharide which, when hydrolyzed, is split into the isomeric monosaccharides dextrose and fructose:

$$\underset{\text{Sucrose}}{C_{12}H_{22}O_{11}} + H_2O \longrightarrow \underset{\text{Dextrose}}{C_6H_{12}O_6} + \underset{\text{Fructose}}{C_6H_{12}O_6}$$

The reaction occurs to some extent upon prolonged boiling of a solution of sugar, but it is greatly accelerated by the presence of an acid or an acid salt such as cream of tartar (potassium hydrogentartrate). Under cold conditions, the enzyme invertase is also used to bring about inversion and is employed to soften the texture of fondant cream centers. Commercial invert sugar, a solution of dextrose and fructose of about 77 % concentration, is sometimes called artificial honey because its composition is similar to that of the natural product.

Corn Syrup, Glucose Syrup, and Liquid Glucose. Corn syrup is the name given in the United States to the product obtained by the hydrolysis of starch. Because different starches, e.g., potato, are used in other countries, glucose syrup seems to be a more appropriate and general name.

In 1811 the Russian chemist G. S. C. Kirchhoff discovered that a sweet substance could be made from starch by treatment with acid. Since then, many syrups of different viscosity, sweetness, and saccharide content, have been produced. Originally, glucose syrup was made entirely by acid hydrolysis under pressure, but now the process has been extended to a combination of acid and enzyme treatment. This has resulted in considerable variation in the proportions of dextrose, maltose, and the higher saccharides, known as oligosaccharides. A more recent development has been the isomerization of the dextrose to fructose by further enzyme treatment (→ Glucose and Glucose-Containing Syrups) [6].

Other Sugars. Dextrose is the ultimate conversion product of starch. The commercial forms are the monohydrate $C_6H_{12}O_6 \cdot H_2O$ and the anhydrous form. Dextrose has unusual crystallization properties and is less sweet than sucrose. These properties are useful in some confections. Fructose is used to a major extent for diabetic candies, because it is not obligatory to insulin.

Lactose is the natural sugar of mammalian milk and is an ingredient of confectionery in which milk products are used, e.g., caramels. Lactose is available commercially and has very low sweetness and solubility.

Sugar Alcohols. Catalytic hydrogenated glucose (sorbitol) has long been offered for diabetics as a substitute for sugar. Because of its pronounced hygroscopicity this polyalcohol is added in small amounts as a humectant for certain items, especially as hydrogenated glucose syrup.

Dental research showed that sugar alcohols, such as maltitol (hydrogenated maltose), lactitol (hydrogenated lactose) and xylitol (hydrogenated xylose) are practically indigestible and therefore noncariogenic. Consequently, confectionery manufactured with polyols was advertised as "good for the teeth" and as "light products", due to their very low calorific value. Most chewing and bubble gums contain exclusively sugar alcohols as sweetening component.

2.3. Other Raw Materials

Although sugars are the primary raw materials, other ingredients play an important part in the formulation of the variety of confections available today.

Milk. Milk in its various forms is used in the manufacture of caramel, fudge, and toffee. Liquid milk is rarely used because of its high water content (87.5 %), and concentrated or dried milk is the accepted ingredient (→ Milk and Dairy Products).

Sweetened condensed milk, skimmed milk, and increasingly whey (with lactose partly hydrolyzed to the sweeter mixture of glucose and

galactose) are considered best by most confectioners. The reason is, that mostly the sometimes poorly soluble lactose is by means of a sophisticated process better soluble (i.e. the seeding technique with ultrafine "seeding lactose" to stabilize the unavoidable supersaturation). Milk powders are sometimes not easily reconstituted, and incomplete reconstitution will result in a rough texture. Condensed sweetened milk has about 40 % added sugar; both this and milk powder may be produced in the nonfat form, in which the original milk fat has been removed. In caramel formulation, milk fat may be replaced by another vegetable fat for reasons of economy. Nonfat milk ingredients are sometimes used in other high-moisture confections where there is some danger of partial decomposition of the milk fat and the risk of rancidity.

Fat. Vegetable fats are used in many recipes and are usually refined and hardened natural oils (→ Fats and Fatty Oils). The one exception is cocoa butter, the natural fat of the cacao bean. The processing of fats is a specialized industry, and unrefined oils are unsatisfactory because of their poor stability and low melting point. Vegetable fats are produced mainly from palm kernel, coconut palm, soybean, peanut, and cottonseed oils, and their melting points are increased either by physical separation (stearines) or by hydrogenation. Palm kernel oil and coconut oil contain high proportions of short-chain fatty acids, e.g., lauric acid, and are called lauric fats. The remaining oils are then known as non-lauric and contain a larger proportion of long-chain fatty acids.

The type of fat influences the texture of confectionery. Catalytically hydrogenated hardened fats give a firm, and unhardened fats a softer quality. Consumers usually prefer the latter, but higher temperatures in summer set limits. This is especially so with lauric fats. Furthermore, enzymatic hydrolysis liberates sensorially unpleasant lower fatty acids. It is therefore better to use special palm oil fractions and (expensive) nonlauric oils from tropical palms (Shea and others). Due to their very narrow melting ranges they give similar cooling effects to unhardened cocoa nut oil.

In confectionery formulations, particularly those with high moisture, great care must be taken in the selection of other raw materials. Cocoa powder, milk powder, egg albumen, flour, and some spices, for example, must have a low microbiological count and be free from fat-splitting enzymes, e.g., lipase.

Minor Ingredients. Many other ingredients are used in compounding the very large number of confections. *Gelatinizing and aerating agents* are materials such as gelatin, agar, pectin, and egg albumen, used for making jellies and whipped or aerated products. *Starches and modified starches* are used as stabilizers and also in the preparation of a class of jellies. *Soy flour* may be regarded as a nutritional filler. *Preserved fruit, jams, and dried fruit* are often included in confectionery for their flavor, texture, and appearance. *Roasted nuts* may be added in a comminuted form, as in marzipan, or in chopped pieces. In the latter case, the confection must be one of low moisture, such as hard caramel, toffee, or nougat. In higher moisture material, like soft toffee, nuts lose their crispness because of the differences in water activity between the nuts and the matrix. *Emulsifiers* are needed to stabilize the fat dispersion when fats are included in syrup-based formulations. The main emulsifiers are vegetable lecithin and mono- and diglycerides.

The appearance and flavor of a food are of major importance. Many *flavors* are used: some are natural, such as the essential citrus oils; others, such as vanillin, are synthetic. Selection and blending of flavors constitute an art, and no food, however well prepared, will be liked if the flavor is wrong. The *color* of food plays a significant part in its acceptability, but the colorant used must conform to legal standards approved internationally or locally. Certain natural colors, such as those extracted from vegetables, have universal approval. In most countries nowadays, the list of synthetic colors allowed is relatively short. Also of importance are sweets containing health products like vitamins, mineral salts, and herbal extracts.

3. Properties and Microbiology of Confectionery

Solubility and Syrup Concentration. The solubility of substances in water varies considerably and generally increases with temperature.

Some materials are capable of forming supersaturated solutions; i.e., more substance is present in solution than would normally be present in a fully saturated solution at the same temperature. A supersaturated solution is formed by first heating the solid and solvent (sugar and water) until a concentrated solution is obtained. If this solution is then cooled without agitation and no solid is precipitated, a supersaturated solution is formed. Such solutions are unstable, and agitation will lead to recrystallization (graining).

The structure or texture of many confections is related to the solubility of the sugars and their ability to form supersaturated solutions. Crystallization may occur from some of these solutions upon agitation. This crystallization can be controlled by addition of other sugars or sugar alcohols and regulation of viscosity, to give many different types of products. Fondants and fudge, which will be described later, are typical examples.

Sugar itself, or in combination with glucose syrup in water, can be concentrated to such a high viscosity by boiling that, on cooling, a stable glasslike product is obtained. This is, in effect, a highly supersaturated solution, containing about 98 % solids and 2 % water, which is the basis of boiled sweet (hard candy) production. No change will occur in this product over long periods of time if it is stored under dry conditions at ambient temperature. The presence of glucose syrup in the formulation improves stability.

The solubility of various sugars and mixtures of sugars plays another important role. The maximum solubility of sucrose, for example, is 67 % at 20 °C, and this solution is still susceptible to microbiological decomposition by yeasts and molds. If the total sugar concentration is increased by combination with other sugars such as glucose syrup or invert sugar, much higher solubilities are ensured. This is illustrated in Table 1 [5].

High solubilities retard or prevent fermentation due to relatively higher osmotic pressure. Modern technology now recognizes that a minimum concentration of soluble solids and, consequently, a lower water activity in the syrup phase of a confection is necessary to curtail any microbial activity. The syrup phase is the liquid portion which contains some of the sucrose, all of the residual moisture, and all of the noncrystallizable carbohydrates. It may also contain a hydrated colloid, such as the milk protein used in fudge.

Water Activity. The equilibrium relative humidity (ERH), also called water activity (A/W), of a substance is the relative humidity of ambient air at which that substance will neither lose nor gain moisture. Temperature must be defined because the ERH of a substance will vary with temperature. Water activity is related to the vapor pressure of a substance, usually a solution. In confectionery, this is normally a solution of sugars, but solids such as starch also have water activity. The value depends on the molar concentration of the aqueous solution, and the values are expressed, respectively, as units or percentages: i.e., A/W 1.0 = ERH 100 % or A/W 0.6 = ERH 60 %.

Knowledge of the water activity of a confection or other foodstuff is important because shelf life will depend largely on this factor. Products with low water activity are likely to absorb moisture and become sticky or otherwise change texture. Those with high water activity will dry out under average climatic conditions.

Table 2. Water activities of some confections

Product	Water activity at 20 °C	Moisture content, %
Wafer biscuits	0.15 – 0.25	<2
Toasted cereals	0.15 – 0.25	<2
Roasted nuts	0.15 – 0.25	<2
Hard candy	0.15 – 0.25	<2
Brittles	0.15 – 0.25	2 – 3
Caramels	0.4 – 0.5	5 – 7
Ungrained nougat	0.4 – 0.5	5 – 7
Gums (jujubes)	0.5 – 0.6	10 – 15
Chewy jellies	0.5 – 0.6	10 – 15
Marshmallow – nongrained	0.6 – 0.7	15 – 18
Soft fruit jellies	0.6 – 0.75	18 – 22
Grained nougat	0.6 – 0.7	8 – 10
Fondants	0.65 – 0.75	10 – 12
Fudge	0.65 – 0.75	7 – 10
Cream pastes	0.65 – 0.75	7 – 10

The water activity of a product influences the conditions required in storage and workrooms, the type of packaging, and the combination of different confections in candy bars. For example, wafer biscuits cannot be combined with a soft fondant because the wafers become soft and the fondant dry. The water activities of some confections are given in Table 2. Each type of product varies somewhat according to moisture

Table 1. Solubilities of mixed sugars in solutions saturated with sucrose at 20°C

Proportion of solids, wt %		Solids content,
Sucrose	Glucose syrup	wt %
100	0	67.1
78.6	21.4	70.0
67.6	32.4	72.0
57.6	42.4	74.0
53.0	47.0	75.0
48.8	51.2	76.0
47.5	52.5	76.1
40.9	59.1	78.0
34.1	65.9	80.0
28.4	71.6	82.0
23.7	76.3	84.0

Solubilities of sucrose and invert sugar mixtures in saturated solutions at 20 °C

Proportion of solids, wt %		Solids content, wt %	
Sucrose	Invert sugar	Saturated sucrose solution	Saturated dextrose solution
100	0	67.1	–
78.6	21.4	70.0	–
67.6	32.4	72.0	–
57.6	42.4	74.0	–
48.8	51.2	76.0	–
47.5	52.5	–	76.1
40.0	60.0	–	73.6
30.0	70.0	–	70.5
20.0	80.0	–	67.7

content and structure. For example, two products can have the same residual moisture content, but if one is a two-phase system such as a grained confection, it would have a higher water activity because the residual moisture would be concentrated in only one part of the confection.

If the composition of a confection is relatively simple, the water activity can be calculated. In former times, desiccators with solutions of special salts, whose vapor pressure values were known, were used to measure the water activity. Nowadays, however, automatic electric devices are used to measure the water vapor contents in a hermetically sealed cell above the sample.

Microbiology. Microbiology plays an important part in confectionery technology. Sugar solutions are susceptible to deterioration by fermenting organisms or mold. Ingredients, such as egg albumen and gelatin in solution, can provide ideal media for the development of molds and bacteria. Powders, such as cocoa, spices, and cereal flours, may contain lipolytic enzymes capable of splitting fat ingredients and causing rancidity. Nuts and fruits often contain ferments and enzymes.

Some enzymes can be usefully employed. Invertase, for example, is used to prepare invert sugar and to bring about the partial liquefaction of fondant centers and to improve the moisture retention, e.g., of marzipan raw mass and formed items of ready made marzipan. Other enzymes are used to reclaim defective products in syrup form by the destruction of pectin and egg albumen residues, which hinder filtration.

Fermentation in chocolate centers was once a great nuisance. In boxed chocolates, fermentation of the fondant centers caused the chocolate covering to burst because of the evolution of carbon dioxide. Syrup exuding from the centers of only one or two pieces could contaminate the whole box. Alcoholic odors also prevailed. Isolation of the organisms responsible revealed that they were mostly osmophilic yeasts (*Zygosaccharomyces torulopsis*) which were able to ferment syrups of fairly high concentration.

While the maintenance of correct syrup phase concentration, previously mentioned, is essen-

tial and generally sufficient to prevent trouble, elimination of the virulent yeasts is also necessary. Good sanitation of plant and vessels is important. Syrup residues in pipelines and closed machinery will develop very active yeasts if the plant is used intermittently. Such machinery should be sterilized regularly with live steam and bactericidal detergent. Certain ingredients, such as preserved fruits, often contain yeasts that remain dormant until incorporated in suitable media – fondant centers, for example. Suspect ingredients must be sterilized by heat, preferably in boiling syrup.

Enzymes, particularly lipase, present a different problem. Many are active at low water activity, but their action is usually accelerated when more moisture is present. This can be a disturbing factor because action initially may be so slow that it is unnoticed, but ultimately, after several months, rancid flavors appear. This phenomenon has occurred with soft nougats containing cocoa powder and egg albumen when lauric fats were included in the formulation. Many ingredients such as cocoa powder, milk powder, and egg albumen are now guaranteed by their suppliers to be lipase free.

Methods for the detection of lipolytic activity are described in publications that also indicate the significance of microbiology in the confectionery industry [10].

4. Types of Confectionery

Some indication of the different types of confectionery has been given in the previous section. The solubility and crystallization properties of sucrose and its combination with other sugars are largely responsible for the physical differences in confectionery products. The major ingredients of all confectionery are sugars. In combination with fats, milk, gelatinizing agents, and minor substances such as emulsifiers and flavors, an extensive variety of confections is possible. The main products are hard- and soft-boiled candies, jellies and gums, foamed products, and nougat and marzipan fillings.

Boiled Sweets and Hard Candy. Hard candies and boiled sweets consist of a solution of sucrose and glucose syrup (the typical ratio is 3 : 2) boiled down to a concentration of about 98 % solids. The hot syrup is cooled to a plastic state at which stage it is flavored, colored, and formed into shapes. The final confections are in a glassy, single-phase, amorphous state, and will remain so under conditions of dry and cool storage. The high viscosity of the supersaturated liquid prevents the sucrose from recrystallizing.

Pulled Confections. The mass of hard- and soft-boiled sweets can be pulled and folded in the plastic state between 90 or 50 °C. Due to the many layers, air is incorporated in tiny bubbles, and the density is reduced drastically. The formerly glassy mass becomes opaque white. In supersaturated soft-boiled masses, this can lead to recrystallization of sucrose, which is often desirable. Pulled soft caramels show better or longer chewability. Addition of 3 – 6 % sorbitol reduces the risk of drying out on the shelf. Pulling in a humid atmosphere or storage of ready-made articles results in a sort of dry fondant, e.g., lozenges, after-dinner mints, or scotch rock.

Fondant. Fondant is a partly crystallized sugar – glucose syrup prepared by mechanical beating and cooling of syrup under controlled conditions.

The syrup is prepared by using a ratio of sugar to glucose syrup of 3 : 1 – 10 : 1, which is dissolved in water and then, to avoid any premature crystallization, carefully cooked up to a concentration of about 88 % solids. This is followed by precooling: a thin stream is continuously drawn into a cold fondant beater. Instantaneously, a creamy mass is formed due to the crystallization process. Final cooling gives a white, stiff paste, which is composed of two phases: a dry phase consisting of minute sugar crystals suspended in the wet phase of sugar, noncrystallizable carbohydrates, and water. The ratio of dry to liquid phase depends on the initial ratio of sugar to glucose syrup and moisture content. Because the moisture is in the wet phase only, the water activity of these confections is relatively high. Some air is also occluded during the beating stage.

The recrystallization of sucrose is the basis of many types of confections, especially fondant. The main factors affecting the growth and formation of crystals of pure substances are the degree of supersaturation, the amount of agitation, the temperature of the solution, the nature

and concentration of impurities (glucose syrup, colloids, etc.), and the shape and presence of existing crystal surfaces (seeds). Crystal growth is a two-step process. First, there is a mass transfer of sucrose molecules to the surface of the crystal; then these molecules aggregate at the surface of the crystal. The warmer the fondant mass becomes on reheating, the more sugar crystals disappear.

Caramels and Toffee. Caramels are relatively low-cooked (113 – 117 °C) confections (typical sugar to glucose syrup ratio of 1thinsp;: 1) [12]. They retain their shape at room temperature because of the presence of swollen milk proteins, especially caseins, and/or gelatin. Their sticky nature is rendered palatable by the presence of an emulsified fat which is also stabilized by the milk protein. Not only does the presence of hydrated milk protein prevent recrystallization of the sucrose because of its extreme viscosity, but the colloidal solution also prevents realignment of the sucrose molecules.

The syrup – milk mixture is cooked to varying degrees to give hard caramels (ca. 5 % moisture) or soft caramels (ca. 7 – 11 % moisture). Additional fat may be added, depending on the amount of fat contributed by the milk ingredient. The typical flavor and color of milk-containing caramels is a result of the Maillard reaction between the milk protein and the reducing sugars during the cooking process. Milk caramels and fruit chews are emulsions and have four phases: sugar solution, sugar or lactose crystals, fat globules, and air bubbles. Their water activity is relatively low.

Because caramels and fudges are emulsions, factors affecting the formation and stabilization of emulsions should be considered. Among these are the amount and type of agitation, the viscosity of the mass, the fat content, and the type and amount of emulsifying agents used (lecithin, milk proteins, etc.). Emulsions can be broken down by mechanical action, chemicals, and heat.

Fudge. If crystallization in caramels is initiated either by agitation or by seeding with the addition of powdered sugar or fondant, a short textured (i.e., one that breaks apart easily) paste is obtained. Fudge is like a fondant and has a dry phase of crystallized sugar and a wet phase of saturated sugar solution with some fat and milk constituents. Like fondants, fudge has a relatively high water activity and is often unstable due to insufficient emulsification. Fudge textures may vary greatly according to the proportion and size of sugar crystals formed, the dispersion of milk solids, and the fat content [7].

Foam Confectionery. This group consists of several different types of confections, ranging from very light with densities down to 0.15, up to almost regular product with 0.9 – 1.2 g/mL. Cones of foamy white mass of the light quality, covered with a thin layer of chocolate are very popular in Europe and are known as Foam Kiss (German: *Schaumkuß*). Other countries prefer heavier foams under the name of marshmallows. Other foamed items are fruit chews and white nougat (Nougat Montelimar). All these confections contain finely divided air cells dispersed throughout the syrup matrix. These air cells are stabilized by the viscosity of the cooled carbohydrate matrix and the aerating agent. In turn, the cold flow of the syrup matrix is slowed by the air cells. During the incorporation of air, the volume of the syrup increases about 250 %. Because of its increased surface area, the normally sticky syrup dissolves quickly in the mouth.

Factors affecting the formation and stabilization of foams are the type and concentration of aerating agent, the amount and type of agitation, the temperature of the syrup, the chemical and physical factors that affect aerating agents, the amount of residual moisture, the type of carbohydrates used, and the amount of air incorporated.

Nougats and marshmallows can be made in grained (controlled crystallization) or ungrained forms and, consequently, may have their carbohydrate constituents in a single phase (ungrained) or in two phases (grained). Nongrained nougats have a typical sugar to glucose syrup ratio of 2 : 3 and a residual moisture content of about 5 %. Foam confectionery of higher density can contain a small amount of fat to aid lubrication. Grained products have a higher sugar content and so a higher density. To bring about partial crystallization, normally fondant or finely ground icing sugar is used. These foams are mostly covered with fatty masses or icing to prevent drying out.

Egg albumin is used as foaming agent for light foams. For heavier ones like fruit chews and white nougat gelatin is sufficient.

Jellies and Gums. Jellies and gums are single-phase, low-boiled (105 – 108 °C), high-moisture (15 – 22 %) confections whose syrupy mass would be quite flowable, but in the presence of some colloidal setting agent, they remain dimensionally stable. The ratio of sugar to corn syrup is about 1 : 1. The recrystallization of sucrose is inhibited by the presence of hydrated colloid and the concomitant increase in viscosity.

Five main types of gelling agents are used in confectionery gels: modified starches, gelatin, agar, gum arabic, and pectins.

Each type forms its own characteristic gel. Starch forms cloudy gels with a chewy, stringy texture. High-methoxyl pectin produces clear gels with a tender short texture. Low-methoxyl pectin acts like a cross between starch and high-methoxyl pectin. Agar gels like pectin, but the gel is slightly more insoluble. Gelatin forms semiclear gels that are rubbery and elastic.

Although the mechanism of gelling is vastly different for each type, the formation of all gels comes about by loss of heat or by chemical bonding. The hydrated colloidal molecules organize and bond together at various sites to form long-chain polymers in which the carbohydrate syrup matrix is entrained and held mainly by hydrogen bonding and capillary attraction between the chains [11].

The gel strength depends on the concentration of colloid, the total solids of the solution, the competition from other sources for water of hydration, chemical bonding, and changes in pH. Because of their high moisture content, jellies have relatively high water activity and tend to dry out. Gums are dried (less than 15 % moisture) versions of starch jellies or gum arabic – gelatin jellies.

Nut Pastes. The prime examples of nut pastes are marzipan (with almonds) [13] and nut nougat (with hazelnuts/filberts). In some countries marzipan may contain other nuts or substitutes. Partly ground almonds are incorporated in a sugar – glucose or invert – sugar syrup by simple mixing and beating. Other pastes contain coconut or apricot kernels (persipan). The nut ingredients must be sterilized in the processing to destroy natural yeasts and enzymes.

Marzipan or "raw marzipan" usually consists of about two-thirds almonds and one-third sugar (invert, corn syrup, and sucrose). Defect-free blanched almonds are kibbled to produce nibs. The nibs, both sweet and bitter (approximately 1 % of total nut weight should be bitter), are blended and then mixed thoroughly with granulated sugar. At the mixing stage, it may be necessary to add water if previously dried almonds are being used (due to moisture loss in the drying process). The mixture is passed through a three-granite roll refiner and the resultant paste is cooked in steam jacketed kettles at 82 – 85 °C for about 20 min to reduce the water activity of the syrup phase to a safer level. The mass is then transferred to shallow water-jacketed pans for rapid cooling and packed after cooling.

Panned Products. Panning is a method of coating a center with layers of chocolate or sugar in a revolving pan. The centers may be nuts, preserved fruits, or other hard or soft items of confectionery. The process often lasts many hours and even days, depending on the desired amount of shell material. A precoating is necessary so create good adhesion between the nuts and the subsequent layers. It must prevent fat reaching the surface and guard against the edges of the pellets breaking or being eroded during the process. Due to the microcrystalline state of the outer sugar coating, such products are especially stable to humidity and have a long shelf life. The coating is usually glazed, which gives a protective quality as well as enhanced appearance.

Pralines, Truffles, and Noisettes. Numerous varieties of pralines, truffles, and noisettes are possible. Many rely on the roasting of nuts in high-boiled (149 – 157 °C) sugar syrup, followed by cooling and grinding to a paste. The natural oil of the nuts plus the very low moisture content of the syrup produce an attractively flavored paste. Incorporation of chocolate, other fats, and alcoholic liqueurs is possible.

Lozenge Pastes and Cream Pastes. Lozenge pastes and cream pastes are simple formulations consisting of a mixture of fine sugar with a solution of a gum (usually gum arabic or tragacanth) to produce a stiff paste

with the consistency of bakers' dough. This is stamped out into a variety of shapes and dried to less than 1 % moisture. Cream pastes are wetter versions of this type, usually made with gelatin and some reducing sugars. These pastes can be layered with other confections such as licorice or low-moisture jellies.

Licorice. Licorice is a special product with a very popular, unique flavor. All formulations are based on an extract of the root of the licorice plant, *Glycyrrhiza glabra*, which grows in the subtropical regions of Asia and Europe. Licorice confections generally take the form of stiff gelatinous pastes which can be partially dried and formed into layers or strips. In some countries, regulations now require health warnings, limited consumption, or reduction of the content of raw liquorice. This is because of the content of glycyrrhizine which can cause high blood pressure.

5. Processes and Machinery for Confectionery Production

5.1. Modern Developments

Confectionery at one time was an art and, within the realm of the experimentalist, remains so to this day. Not so long ago, in some factories skilled employees customarily made their own modifications of recipes as they went along. To some extent, this was necessary because the raw materials they worked with were by no means consistent.

As the size of factories increased along with the costs of raw materials and labor, more scientific and mechanical methods became necessary. The creative art of the experimentalist then had to be transferred to economic production without loss of quality. Initially, this meant increased batch size with mechanical handling and, sometimes, automatic weighing. Batch production is now giving way to continuous production, in which machinery from other industries is often adapted to confectionery processes.

5.2. Production of Typical Confectionery Products

5.2.1. Fondant

Fondant is a relatively simple primary product prepared from sugar and glucose syrup, with sorbitol or invert sugar included occasionally. By means of a secondary process of partly remelting and the inclusion of other ingredients such as preserves, flavors, and egg frappé, fondant can be transformed into a large variety of confectionery pieces suitable for coating with chocolate.

5.2.2. Production of Fondant

The basic solution has a concentration of about 80 % solids and is then further concentrated to 88 % by boiling to 117 – 119 °C. The syrup is cooled to 38 – 42 °C; it is now a supersaturated solution and, in this condition, is delivered to a beater – cooler, known as tablier machine. Beating is performed in a water-cooled tube with rotating internal spindles fitted with intermeshing pegs. Extreme agitation deposits excess sugar from solution in the form of minute crystals. This causes the evolution of much latent heat, which must be removed to avoid redissolution of the sugar. The sugar crystals in the cooled fondant from the beater should have a maximum diameter of 10 – 15 µm. At one time, this process was carried out manually by vigorous mixing of the syrup on a large marble table with a spadelike implement – a laborious task. Large machines are now employed, with outputs in excess of 1000 kg/h.

The sugar – glucose syrup is usually concentrated by means of a scraped-surface, thin-film, continuous cooker. Cooling is accomplished either by a large, rotating drum that is internally water cooled (Fig. 1) or by a water-jacketed tube with an internal screw.

5.2.3. Casting Fondant Articles

To prepare small fondant pieces for subsequent coating, the fondant must be partly remelted so that it can be cast into molds or chocolate shells. The conditions for remelting must ensure that only a small percentage of the crystals are dissolved. This process consists of heating

Figure 1. Baker – Perkins fondant machine
a) Premixer; b) Cooker; c) Cooling drum; d) Fondant beater; e) Creme mixer; f) Second stage mixer (color, flavor); g) Discharge

the fondant with a small amount of syrup of the same composition as the fondant or preferably sorbitol. The maximum temperature should be 65 °C. This will give the required fluidity without destroying the crystal phase.

This process temporarily lowers the viscosity and permits depositing into molds. Upon cooling, the excess sucrose in the liquid phase recrystallizes onto the existing crystal sites and cements them into a rigid structure. This occurs especially at the surface, where more evaporation has taken place, and permits the cast fondants to be handled. The remelting can be carried out in a steam-jacketed kettle or continuously in a tube provided with a heating and mixing system. At the same time, flavors, colors, fruit acids, and preserves are included. The established method of casting is to use starch molds. The large automatic machine developed for this purpose, called a mogul, is shown in Figure 2.

In this machine, shallow trays are filled with dried starch and printed by pressing a multiple former into the starch, which retains the impression of the shape of each protrusion when the printer is removed. By means of a hopper and multiple-pump system, the correct amount of melted fondant is deposited into each impression. Trays containing the starch and deposited pieces are removed automatically, stacked, and stored until the fondant has set. The starch trays containing the set fondant are fed to the front of the mogul, which empties the trays through a sieving and brushing system that completely removes the starch. The pieces of fondant are then delivered to trays and, subsequently, to a chocolate enrober for covering.

During the sieving process, the separated starch is returned to a drier and then used to refill the trays. The mogul has the disadvantage of being a very dusty operation, which leads to difficulty in maintaining a high degree of sanitation in the production area.

Modern developments utilize other methods of forming such as extrusion or molding. The use of metal molds was developed by Baker Perkins in conjunction with Cadbury. Each mold impression is coated with a release agent and provided with minute holes. After depositing, the molds are cooled and the pieces are ejected onto a belt by compressed air. They are then fed directly to an enrober. The rubber mold system uses flexible silicone rubber molds. Silicone rubber has exceptional nonstick properties and is very heat resistant. Continuous depositing, cooling, and demolding plants are now used for toffees, caramels, and some hard candies.

5.2.4. Soft-Boiled Sweets, Fudge, and Toffee

Sugar, glucose syrup, invert sugar, sorbitol, milk products, fat, and emulsifiers are the essential ingredients of this group.

For the production of milk caramel the ingredients are mixed with sufficient water and boiled over a gas burner or in a steam-jacketed kettle. Soft caramels are boiled to 118 °C, medium to

Figure 2. NID high speed mogul molder
a) Stacker; b) Depositor; c) Starch molder; d) Feeder; e) Suspended starch sprinkler; f) Starch sifter

122 °C, and hard to 130 °C; however, these figures are subject to some variation. In pan boiling, flavor develops over a period of 15 – 20 min and arises from the Maillard reaction between the milk protein and reducing sugars. The milk ingredient is important, and sweetened condensed milk, skimmed milk and whey are favored by most manufacturers.

Milk powder is also used, but this must have high solubility and be adequately hydrated in water before use. Modern cooking methods are continuous, but when cooking time is much reduced, a caramelizer must be included in the plant. This consists of a vessel in which the cooked caramel is held at a temperature of about 120 °C for 15 min. Cooking time in a continuous cooker can be as little as 1 min, which is insufficient for Maillard flavor development.

Many continuous cooking plants exist; most are based on the heating of a thin film to concentrate and cook the original mixture quickly. Immediately after cooking the product must be cooled by discharge onto a metal table, a water-cooled belt, or a cooling drum. Fruit chews do not normally contain milk constituents but gelatin. They are often aerated by pulling or adding frappe down to densities of 0.8 – 1.2 g/mL.

To make fudge, caramel is produced in the manner described above and then cooled to 80 °C. Fondant is added in the proportion of about 10 % and mixed in well. This mixture is discharged onto a table and allowed to cool until it sets to a short texture because of the gradual formation of a sugar crystal lattice.

In continuous fudge manufacture, the fondant may be extruded into a trough in which the caramel is being mixed and discharged. In the United States toffee is a high-cooked version of caramel but with a lower milk content. In Europe toffee is a chewable soft candy, rich in fat and milk constituents. Toffee is a high-cooked version of caramel but with a lower milk content.

5.2.5. Forming of Bars and Small Units from Soft-Boiled Masses

Soft milk boilings, fruit chews, and fudge can be formed into pieces by cutting, extrusion, or a combination of both. They can also be formed by the batch roller and rope-forming system described for boiled sweets, or it may be deposited into the silicone rubber molds mentioned under fondant. The principle of extrusion has been applied a great deal to confectionery products in recent years, particularly to plastic materials such as caramel, fudge, nougat, and fondant.

Extrusion machines operate by means of fluted rollers which are fed by a hopper and force the material through multiple orifices. The extruded confection may be sliced off into small pieces by wire or knife just beneath the orifices, or it can be allowed to form ropes. The ropes are subsequently guillotined into bars for feeding to a chocolate enrober.

5.2.6. Boiled Sweets, Hard Candy, Brittle, Croquante, and Butterscotch

Boiled sweets mostly have a relatively simple formulation consisting of sugar and glucose syrup. Some, however, contain milk product, cream, licorice, etc. High-quality sugar must be used. The glucose syrup varies in type and proportion according to the method of cooking and

the kind of hard candy required. Cooking may be by open pan, thin-film continuous cooker, or vacuum cooker (Fig. 3).

Figure 3. Vacuum cooker for hard-boiled sugar masses

In small-scale production, a gas-heated or steam-jacketed pan may be used. The batch is boiled to ca. 150 °C under atmospheric pressure or cooler under vacuum. Care must be taken to avoid any source of graining. The batch is poured onto a cooling table where it reaches a plastic condition; the outer edges of the batch are turned inward to give even cooling. Flavor, color, and acid are added to the center of the batch and incorporated by folding and turning; the mass must retain an even temperature and plastic condition. The whole of the material is then transferred to a group of machines consisting of a batch roller, a rope sizer, a former, and a cooler (Fig. 4).

The batch roller reduces the large piece to a rope which is fed through the sizing rollers to yield a uniform diameter. This rope is then delivered to a forming press which shapes and discharges individual pieces according to the design or the dies. These pieces pass along a conveyor supplied with cooling air. In large-scale production, syrup is boiled either by thin-film cookers or in vacuum pans and is conditioned prior to shaping by mechanical kneaders or water-cooled conveyors provided with plows. Flavors and colors can be fed into the syrup in continuous fashion. Some boiled sweets may be deposited into metal molds which are cooled; the pieces are removed by ejection pins in the mold. An interesting process is the technique of producing hard-boiled sweets with soft centers. A filling tube is injected into the hot plastic lump, which rotates in the batch roller. A pump presses the liquid filling into the center, so that, after passing the cutting station, each sweet has 20 – 25 % filling. It is important that during cutting the open ends are closed by squeezing the still plastic material together.

Because it is impossible to produce boiled sweets only with sugar, it is an old practice to add weakly acidic hydrolyzing salts to the batch. This leads to a certain degree of inversion of sucrose and formation of invert sugar, which helps to prevent the otherwise unavoidable recrystallization. Substances like potassium hydrogen tartrate are often called "doctoring agents", and sweets made by this technology, "all-sucrose candies". More common, however, is the addition of glucose syrup, which prevents recrystallization in the same way and without the risk of over-inversion.

Hard candy may be pulled by submitting the plastic mass to rotating and intermeshing cranks. This process occludes air and produces an opaque and shiny appearance.

Plastic masses of different flavors and colors can be combined and laminated to produce striped sweets. Both these laminated masses and the pulled candy can be shaped by the forming system previously described.

Brittle, butterscotch, and croquante are all high-boiled (149 – 157 °C) products. They are always cooked on a fire which gives the necessary high temperature (about 155 °C) and caramelization. Nuts may be included in the cooking process.

5.2.7. Light Foams, Marshmallows, and White Nougat

All these products are aerated. They can be made batchwise or in continuous processes (Fig. 5). The base is made from sugar, glucose syrup, and invert sugar or sorbitol. Aeration is brought about by including a foam or frappé produced from egg albumen, gelatin, or from modified milk or soy protein.

Products with high aeration (0.15 – 0.2 g/mL) are very fragile, and their manufacture requires great skill. Their shelf life is short, although they are covered with a film of chocolate ("foam

kisses"). They are foamed with special fractions of egg albumin in powdered form.

Marshmallows – confectioneries with densities of about 0.4 – 0.5 g/mL – can be made with gelatin or egg albumin as foaming agent. White nougats like Torrone and Nougat Montelimar are even heavier and very tough. They are prepared with nuts, dried fruits, etc. The egg albumin powder and the gelatin have to be dissolved with some sugar, preferably by soaking with cold water for a period. Working batchwise, the foaming agents are beaten separately in a mixer with horizontal or planetary arms. Finally the hot sugar/syrup is added (frappé).

Modern methods use pressure beating, in either a batch or a continuous machine. The syrup and the aerating agent are beaten under pressure in a closed container that is controlled in time and pressure. Release of pressure is used as a means of discharge. With the continuous

method, the syrup, air, and egg – gelatin solution are each metered to a rotor – stator mixer against a back-pressure valve through which the foam is continuously discharged.

Marshmallows can be made with a variety of textures. Some may be deposited into starch as fondant; others are extruded into ropes onto a moving bed of starch and subsequently cut into pieces. Because of their lower moisture content, nougats need more powerful mixers, but the first process is similar to the atmospheric or pressure beating used for marshmallows. In the final process, fat is included together with other ingredients such as cocoa powder, milk powder, flavor, preserved fruits, and icing sugar. This mixing must be as short as necessary to completely disperse the fat because the fat acts as an antifoam and tends to reduce aeration.

Both nougat and marshmallow can be made to a short texture by the inclusion of icing sugar. This will aid crystallization of the sugar ingredient in the base syrup as well as provide a shortening effect. Air inclusion may have deleterious effects on flavor because of oxidation. Some essential oils will develop an objectionable taste and the fat may become rancid. The risk of microbiological deterioration also exists.

5.2.8. Jellies and Gums

Products of this group are either easy to bite, short and soft in texture, or gumlike and elastic. They are manufactured in a variety of textures, partly depending on the residual moisture content and partly on the gelatinizing agent used (Fig. 6) [14].

Pectin Jellies. Pectin jellies are considered by many to have the best texture, but they require careful technical control for the best results. Pectin is the natural gelling substance in fruit and is responsible for the setting of jam. To form a jelly, pectin must first be dissolved fully in water, then sugar and glucose must be added and the syrup boiled to 75 – 78 % solids. This is followed by the addition of citric acid to give a pH of 3.3 – 3.6. The hot mix is deposited at not less than 90 °C within a short space of time.

Normally, pectin jellies are cast in starch like fondant, but modern developments have made metal mold depositing possible. Two types of pectin are used commercially – high methoxyl and low methoxyl; the names denote a difference in the pectin molecule. High-methoxyl pectin requires an acid pH to give a correct jelly; low-methoxyl pectin needs a calcium salt to set it. Pectin jellies usually require the addition of a buffer salt such as sodium citrate to control the rate of setting. A good set is obtained with 1 – 1.5 % pectin in the jelly.

Gelatin Jellies. Gelatin jellies are relatively simple to prepare. The basis is a sugar – glucose syrup, and the quantity of gelatin used varies from 4 to 10 %, depending on the texture required. The essential factor is to soak the gelatin first and add it to the syrup after the syrup has been boiled to the correct concentration. Usually gelatin solution must never be boiled although modern cooking techniques have eliminated the problem of burning. The texture of jellies with gelatin is not very satisfactory. The higher the amount of gelatin, the tougher the jelly.

Agar Jellies. Agar is extracted from seaweed (red algae like Gelidium and Gracilaria). Even small percentages in a syrup form softly structured jellies. Agar is dissolved by boiling, but flavor acids must be added at the end of the boil and after cooling or the strength of the gel will be lost. Agar gels have a texture that is somewhat short, and some of them do not disperse readily in the mouth. Starch casting is usual, but agar jellies can also be set in slabs and cut into pieces.

Starch Jellies. Products made with modified starches are not really jellies, but intermediate between jellies and gums. Starch in its various forms has achieved much importance in the modern confectionery industry, in part because it can be used to produce low-cost jellies. The texture of some of these, however, leaves much to be desired. Modified starches such as boiling starch and high-amylose starch are normally gelatinized in jet cookers. A slurry of the starch and sugars is subjected continuously to high-pressure steam in a small chamber at about 170 °C. Mixes with low water content can be cooked successfully by this method. Starch casting is generally used for these jellies.

Semicontinuous automatic weighing of all raw materials in Contigrav (a) and continuous feeding to the mixer Coil Cooker 3606 (b); continuous cooking to the required concentration (with or without vacuum). Continuous feeding of the product to the depositing plant [Mogul hopper (c)]

Gums. Gums, wine gums, fruit gums and the like were prepared originally with gum arabic as the base, but gelatin, agar, and starch are also used today. High-quality items with the real firm bite, however, are still prepared with gum arabic in high percentages. Gelatin is used up to 25 – 40 % to achieve the desired texture. A gel is prepared in a manner similar to the jellies mentioned previously, but after casting in starch, the trays are stored for up to six days at 50 °C. After removal from starch, the gums are glazed by a process of steaming, drying, and lubricating.

5.2.9. Panning

Panning is an important part of confectionery production, and very large amounts of panned goods are now manufactured [15]. The two types are chocolate panning and sugar panning, but sugar panning can be further subdivided into hard and soft panning.

Panned confectioneries are always made in rotating coating pans. They have a special shape and are inclined so that when it is rotated, the confectionery pieces will roll round the inside of the pan and not slide. The shape and inclination of the pan can be varied to suit the product.

Whether the coating is chocolate or sugar, the operation is similar. The product to be coated (for example, almonds or hazelnuts) is placed in the pan, which is then set in motion. While the nuts are rotating, they are first coated with a sealing solution which may be gum arabic. Warm air is injected into the pan until the gum solution is dry. For chocolate panning, liquid chocolate at about 35 – 36 °C is applied intermittently by spray or drip feed and set by cool air. Each layer must be set before application of the next. Thus a thick coating is built up.

For hard sugar panning, supersaturated sugar syrups are applied in small amounts and then dried with air. By this means, a hard sugar coating is built up over a long period of time. For soft panning, the center is different and may be a preserved fruit, jelly, or paste. The outer coating consists of glucose syrup, finely granulated, and icing sugar. With all panned articles, a final glaze is applied. This may consist of an underglaze of syrup plus a gum, followed by a wax or edible shellac coating.

5.2.10. Other Products

Some products, such as chewing gum, chewing sweets, comprimated products and licorice, are almost special industries in themselves. Chocolate technology is closely integrated with confectionery [16]. The principles of chocolate tempering and enrobing should be fully understood by the confectionery technologist. Many confectionery manufacturers do not make their own chocolate but purchase it from companies that have large-scale plants and can produce it with maximum economy (→ Chocolate).

6. Packaging, Storage, and Economic Aspects

Package. The wrapping of a candy bar or, in fact, any confection, serves three main purposes:

[d] Estimates.

(1) to provide a container; (2) to describe and advertise the product; (3) to protect the product.

Display in a supermarket is usually on multiple shelves or near the check-out counter (cashier). At both places, the contents of the package must be easily identified and, when necessary, the age of the product ascertained. The wrapping itself should have protective qualities. The material of the wrapper must prevent access of moisture or extraneous odors. The wrapper should be strong enough to resist damage by normal handling and preferably be heat-sealed. Sealing also discourages insect entry and tampering by humans.

Materials to meet these demands and machinery to seal the packages at high speed have been developed. Special laminated plastic films such as polyvinylidene chloride and polyethylene and many other plastics have been used to satisfy protective requirements.

High-speed wrapping and printing sometimes result in a serious problem with residual solvent odors which contaminate the product. Sufficient airing of the freshly printed wrappers, effective quality management in combination with certification according to ISO standards and application of high-tech laboratory equipment has reduced this defect.

Storage. With protective packaging of confectionery products, many problems have disappeared, with the exception of heat damage. No normal protective wrap will guard against excessive heat. Damage in storage often occurs because of failure to recognize the need for a strong enough outer carton or to avoid stacking loads too high. Many large companies now have computerized stockrooms where packages and loads are handled correctly and stock rotation is controlled accurately.

Economic Aspects. The chocolate (→ Chocolate, Chap. 9.) and confectionery industry is extremely large worldwide. Table 3 gives the sugar confectionery consumption from 1992 to 1997 in Europe. Table 4 is representative of the number of companies and sales volume in the EU.

1. Bricks and Structural Tiles

Bricks and structural tiles are mass-produced ceramic products requiring large amounts of raw materials for manufacture. Brick and tile making is mostly a low-value industry, but is nevertheless often problematic because of the dependence on suitable clay close to the manufacturing facility. These raw material problems, the increasingly higher quality standards, and competition from other building materials necessitate costly but economical manufacturing techniques.

1.1. Classification

In order to give an idea of the essential features of the various products, some porosity and strength values specified in the German DIN standards are given in the following.

Bricks. Ordinary bricks constitute the largest fraction of total brick production. They have a porous body. If there are no special requirements in regard to appearance or resistance to weathering, they are called *inner-wall bricks*, or *backing bricks*, and can be solid or hollow. For hollow bricks there are requirements for strength (4 – 28 MPa) and a brick bulk density of 1.0 – 2.2 kg/dm^3. (The brick bulk density is calculated by dividing the mass of the dried brick by its

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a07_425

volume *including* all channels, finger holes, and mortar pockets, or frogs.)

One special variety of brick is the *insulating brick* used to reduce heat flow [10]. For these the strength specification is 2 – 28 MPa. The brick density must be only 0.6 – 1.0 kg/dm^3. The porosity is increased by adding materials that burn during firing. Insulating brick can be as large as $49 \times 30 \times 23.8$ cm.

Progress is being made in producing building components with height equal to the height of the room. These are known as *brick planks* [11] and are produced as monolithic pieces with an extrusion press.

If the brick has surface and color suitable for facing and the brick is able to withstand frost, the brick is classified as *face brick*, or *facing brick.* If the average compression strength is ≥ 45 MPa, the brick is ranked as *extra strong.*

Clinker Bricks. To achieve clinker classification, the bricks must have a specified degree of sintering (water absorption below ca. 7 wt %), average compression strength > 35 MPa, and a *body density* > 1.9 kg/dm^3. (The body density is calculated by dividing the mass of the dried brick by its volume *excluding* all channels, finger holes, and mortar pockets.) Extra strong clinker bricks must have an average compression strength > 45 MPa.

Ceramic clinker bricks, which are manufactured from high-quality nonporous sintering clays, are face bricks having a water absorption capacity ≤ 6 %. The net density must average ≤ 2.0 kg/dm^3, and the average compression strength must be > 75 MPa. Furthermore, the surface must have a specified abrasive hardness and colorfastness in light. The clinker materials also include bricks for sewer construction, paving stones, and sintered flagstones, for which the water absorption must be below 3 – 6 %, depending on the intended use.

Roofing Tiles. Roofing tiles are manufactured to produce their particular shape, sometimes with their natural color and sometimes with a slip coating or a glazed finish (see Section 1.9.). They are manufactured by extrusion or stamping. They usually have a porous, unsintered structure, and to be weatherproof they must be accurately shaped, water impermeable, and able to bear sufficient load.

Special Products. There are a number of porous products other than roofing tiles: wall tiles, floor tiles, drain pipe, and cable conduits.

Expanded clay is a special product [1], [12], [13], usually consisting of spherical particles with a diameter of 1 – 16 mm, having a densely sintered surface and an expanded finely porous structure. The quality of this product depends critically on the packing density of the particles, the density of the outer skin and the uniformity of the pore structure. The bulk density varies from 0.3 to 0.8 kg/dm^3, permitting use as an aggregate in light concentrate or as an insulator for walls and floors.

Typical brick and tile products are shown in Figure 1.

1.2. History

Brick manufacture is one of the oldest mass-production trades. Excavations along the Nile have revealed the earliest bricks, estimated to be 15 000 years old, which were made by hand from Nile mud, sand, and powdered straw. The dimensions were approximately the same as those of the standard bricks used in Germany. They were air dried and used to construct small dwellings. The oldest description of brickmaking (ca. 1500 B.C.) was also discovered in Egypt, all stages of the process being described, from clay extraction to air drying of the product [1].

Bricks and brick fragments 6000 years old have been excavated in Mesopotamia. In Uruk (Sumeria) both air-dried and fired bricks have been found, as well as colored mosaic pieces of fired clay, these dating from 3100 to 2900 B.C. The magnitude of the industry may be appreciated from the 9.5-km brick city wall with 900 towers.

In the Punjab region of India there are remains of brick towers 8 m in height and dating from 2500 B.C. Other well-known examples are the glazed and embossed brick walls of Babylonia and Persia, and the 5000-year-old houses of Habuba Kabira, on the upper Euphrates, constructed of air-dried, die-formed bricks and provided with a sewer system of fired clay (Fig. 2), including sockets, pipes, and U-sections [14].

The 800-year-old pueblos of the American Southwest are recent by comparison. They were

Figure 1. Typical brick and tile products

built four or five stories high from dried adobe bricks. A complex of buildings could contain up to 800 rooms [15].

As reported by Pindar (5th century B.C.), roofing tiles were invented in Corinth: later, these were adopted and used over the entire western European part of the Roman Empire. The words tile (English), tuile (French), Ziegel (German), and tegel (Dutch) are all derived from the Latin word for roofing tile, *tegula.*

Eaves trough tiles, antefix tiles, and ridge tiles up to 50 cm × 100 cm were produced. The tile shapes and methods of attaching them have changed little since Roman times [1].

1.3. Raw Materials

A great variety of clay sediments are used, ranging from loose to compact in consistency. The principal raw materials are loams, clays, marls, mudstone, shale, and slate together with smaller quantities of boulder clay, loess, and sand [16]. They can contain all types of suitable clay minerals (layered silicates → Clays), such as illite,

Figure 2. Ceramic sewer pipe and stone-covered sewers in a 5000-year-old house in Habuba Kabira (Courtesy of the Deutsche Orient-Gesellschaft)

sericite, kaolinite, chlorite, and montmorillonite. Quartz is an important component and is always present, and there can also be considerable amounts of calcite, dolomite, and iron compounds. The composition and particle size are the two principal factors that determine the nature of the products.

Figure 3. Dilatometer curves
a) Marl clay (calcareous); b) Clay (noncalcareous); c) Slate clay

Some constituents are harmful, mainly coarse pyrites and limestone inclusions, which can cause spalling; sulfur compounds, which can cause efflorescence [17]; and large carbonaceous particles and plant remains.

Whereas common bricks may be manufactured from fairly low-quality brick clays, large hollow bricks require adequate plasticity of the clay body. For hollow bricks, clays and marls are used primarily, sometimes mixed with loam and shale. Other products with a porous structure are produced from these raw materials, e.g., face bricks, paving bricks, roofing tiles, drainage pipes, and cable conduits. Clinker, with its impervious or near impervious structure is produced mainly from shale and stoneware clays. Shale clay tends to be used for the manufacture of clinker face bricks, high-compressive-strength solid or hollow bricks, paving bricks, and sewer channel bricks. Stoneware clays are the first choice for high-quality face bricks and for split clinker flags and flooring tiles (see Section 2.7).

Additives. Additives improve both the manufacturing process and the products. A variety of combustible organic materials are used, such as foamed polystyrene, sawdust, powdered straw, powdered brown coal, and materials with organic content including oily filtration aids

(fuller's earths), oily metallic hydroxide slimes and coal washery refuse. These additives may increase the porosity and thus the insulating quality of the brick. Furthermore, the amount of fuel required for firing may be reduced [18–20].

Powdered limestone or chalk may improve firing properties, increase porosity, and lighten the color [21], [22]. Powdered slags from blast furnaces or power stations are opening agents that add strength, while making the plastic mass leaner; glass powder is also a suitable additive [19]. Iron oxide powder and various sludges provide color [23].

As a consequence of ever more stringent quality requirements, some high-quality clay is commonly used for brick manufacture.

Raw-Materials Testing. Owing to the wide variety of raw materials, effective tests for suitability and effective methods for optimizing the proportions are needed.

Raw materials are characterized by their geological origin and condition as well as by mineralogical analysis, particle size analysis, and to a limited extent chemical analysis. Harmful constituents, e.g., coarse inclusions that could cause defects, salts that could cause efflorescence, and compounds that could produce noxious substances on firing, must be revealed by testing [17], [24], [25].

To assess the workability of the unfired mass, the water requirement, the relationship between water content and stiffness (Pfefferkorn method), the tensile and shear strength (Linseis method), the shrinkage on drying, and the transverse strength after drying are needed. Also needed is knowledge about how sensitive the material is to the drying process (Bigot curves showing shrinkage versus water loss, see Sections 1.6 and 2.6) and the water permeability.

The expected firing characteristics and properties of the fired body can be obtained by dilatometry, differential thermal analysis (DTA), thermogravimetric analysis (TGA), and test firings. Firing at various peak temperatures allows determination of the tendency to form reduction cores, the ability to retain shape (extent of softening at high temperature), the shrinkage on firing, water absorbancy (vapor and liquid) of the fired body, density, and color [1], [26].

Examples are given in Figure 3 of dilatometer curves for three different raw materials, showing the expansion and contraction during firing.

These testing methods are especially useful for working out optimum proportions of various clays and additives. In addition, there are some tests used for production control that are designed individually for particular manufacturing processes [27].

Clay Winning. The raw materials for brick manufacture are nearly always obtained by opencut mining. To reduce costs, all the various strata are usually mined, and these strata are mixed to the extent possible during the extraction process. The higher the quality of the products, the more worthwhile it is to separate the valuable clay strata from the lower value inclusions and strata.

For the extraction of soft or crumbly materials, especially when the strata are horizontal, bucket excavators are suitable because each bucket scrapes away thin layers of material from top to bottom of the strata, thoroughly mixing them in the process (Fig. 4). These excavators are, however, not especially mobile and are unsuitable for selective extraction of materials. For mainly vertical strata, bulldozers or scrapers achieve the best mixing effect (Fig. 5). These can also be used to transport the material over short distances.

Dragline excavators mix somewhat less effectively, but can be used where the geological formations are complex. A dredging shovel suspended by a cable from a boom is thrown outwards and then dragged back upwards through the material being extracted.

Power shovel excavators (Fig. 6) are widely used. These were formerly cable operated, but are now usually hydraulic and normally fitted with a grab. An advantage of shovel machines is their great mobility. Unwanted strata (gravel, chalk, etc.) are removed relatively easily, and lenticular deposits of clay can be extracted. Heavy power shovels have been used to extract diagenetically solidified raw materials such as shale. Hard clay stone must first be broken by explosives. Transportation of the materials within the mining area and to the processing area is by rail, belt conveying, or truck, depending on the distance [1].

1.4. Preparation

Raw materials and mixtures that are variable in consistency and composition are converted into homogeneous, easily moldable masses of uniform quality [28]. If the available equipment is unable to achieve adequate mixing, and therefore the quality required, a premix should be carried out with a suitable extraction process in the mine or with a large-scale mixer, e.g., one for mixing stocks of materials. Coarse, hard materials, such as limestone, pyrites, and quartz, should be removed as completely as possible; otherwise, the cost of producing a fine product is too high. Diagenetically hardened clays, such as shale, can be stored in the open air; the weathering that takes place favors deflocculation of the clay.

The choice of the preparation process is determined by the type and condition of the raw material and the end product. There are three processes: wet, semidry, and dry. The wet process is used most often.

Wet Processing. Most raw materials for brick manufacture have a high natural moisture content as mined. This moisture may have to be carefully supplemented during the preparation process with gauging water if the product is intended for wet molding. The constituents are precisely measured out with charging boxes (Fig. 7 A and 7 B) and wet-milled. Edge runner mills are still commonly used for this purpose, their heavy rollers (Fig. 7 C, b) effectively grinding quite hard clay stone. Only the hardest raw materials need an initial crushing operation with a roll crushing mill. The edge runner mill also acts as a mixer to some extent, incorporating most of the water needed to give good molding properties. The intensity of the size reduction and mixing processes is determined by the number and size of the slits in the sieve plate (c).

If necessary, the product may be further treated with coarse and fine crushing rollers,

Figure 7. Mixing and grinding machines

D) Rolling mill: a) Conveyer belt from the kollergang; b) Rollers; c) Conveyer belt to the next processing step

which reduce the particle size to < 1 mm (Fig. 7 D). A few installations include a series of about three roll crushers, which progressively reduce the particle size of the raw material mixture. Another technique is to treat coarse material, while water is being added simultaneously with cone-shaped rim gears, which produces a fine, soft plastic mass. Lean mixtures, which break down more easily, may usually be molded directly after mechanical crushing. Very plastic materials are better processed intensively with mixing and homogenizing machines to break up the compressed clay mass into small pieces.

The material is often put into temporary storage in large containers, bunkers, or aging towers in a moist condition. This procedure encourages deflocculation and homogenization of the clay, and tends to prevent operating problems. It also ensures a stable supply and good cross mixing of material. However, prolonged storage of moist material is not advisable if pyrite is present, because this slowly oxidizes to sulfate, which produces severe efflorescence on drying.

There are mixing and homogenizing machines specially designed for the molding process, e.g., circular feeders and single and double trough mixers. They facilitate the addition of measured amounts of powders (e.g., barium carbonate), materials to promote porosity (e.g., polystyrene), and water or steam to heat up the mass (hot preparation). These machines, like the aging tower, fulfill two separate functions [1], [10].

Semidry and Dry Processing. These procedures are mainly used in the production of clinker flagstones, more rarely for face bricks, pipes, and clinker paving slabs. The best raw material for these products is shale, which has a low natural moisture content, < 10 wt %, and therefore does not need to be dried. If shale has a high quartz content it is very abrasive and perhaps should be wet ground in a heavy edge

runner mill. Dry processing is used from time to time in the manufacture of high-quality face bricks and floor tiles when highly plastic, moist clays, e.g., stoneware clays, are used. However, a large proportion of the water must be removed before processing.

Depending on the type and hardness of the raw material, various types of size reduction machinery are used: jaw crushers, kollergangs, impact mills, hammer mills, pendulum roller mills, and centrifugal grinders.

Moist raw materials can be dried during milling with the waste hot air from driers or kilns. When harmful inclusions interfere with the manufacture of high-quality products, these combined grinding/drying machines can also pay for themselves by finely milling these particles in the presence of high clay moisture contents [29].

An advantage of dry processing is that the material being milled can be mixed with the precise proportions of powdered additives required, e.g., powdered clay, brick dust, sand, metallic oxide pigments, etc. Then the product can be transported satisfactorily by screw conveyor and is easy to remove from the storage bunkers in a uniform manner.

Dry processing is especially suitable when dry pressing is to be used. If necessary, the material is carefully moistened and granulated on trays. In order to obtain the correct granule size and to cause densification, pan granulators may also be used.

1.5. Molding

1.5.1. Processing

The molding process most commonly used for brick is *wet pressing.* Other processes are stiff mud pressing for low water additions and the semidry and dry pressing processes. The choice of pressing process is determined by the raw materials and products [1], [30], [31]. The most suitable moisture content depends mainly on the type of raw material to be treated.

Wet Pressing. Materials with sufficient plasticity may be molded by wet pressing using extrusion presses or stamping presses to form almost all brick products, including wall slabs and flagstones. The correct water content (tempering water) is between 20 and 30 wt % and depends on the ratio of clay to nonclay material. Whereas ordinary bricks tended to be soft pressed, more recently there has been a tendency toward stiff pressing. The reasons are improved green strength and therefore dimensional stability, and a saving in energy for drying.

Stiff Pressing. Good plastic masses and fairly soft shale are sometimes molded by stiff pressing. The gauging water is then ca. 15 wt %. Mixtures that contain lean and silty minerals and low-quality clays are unsuitable because their molding properties are extremely sensitive to slight variations in moisture content. Stiff pressing, particularly for hollow bricks, requires high pressures and powerful presses. The main advantage is that the molded pieces are stacked on the kiln car immediately after forming and then can be passed through the dryer and kiln without repeated handling. This method of molding is not so suitable for making products with many holes, e.g., with thin webs or thin walls, nor can it be considered for pressing insulating bricks whose porous materials would be destroyed by high pressure.

Soft Mud Brick Making. By means of strickling machines, lean or silty clay mixtures that are unsuitable for the extrusion process may be molded to give face bricks with a very rough (rustic) surface to fulfill special architectural requirements or for restoration work (sometimes even hand molding is employed). These processes require soft plastic masses with gauging water contents of 25 – 35 wt %.

Semidry Pressing. Semidry pressing, which is, for example, commonly used in Great Britain to make bricks [1], requires a gauging water content of 10 – 15 wt %. As with stiff pressing, the molded pieces may be handled without difficulty and stacked directly onto the kiln cars without predrying. Compared to other molding processes, preparation of raw materials is less costly, normally only involving particle-size reduction and incorporation of the required tempering water.

Dry Pressing. Materials for dry pressing, which consist of shale, require as a rule 5–10 wt % gauging water. Stoneware clays and other rich clay materials, or those with complicated shapes, can have a water content exceeding 10 wt %. Diagenetically solidified clay stones, e.g., shale, are especially suitable for dry pressing with low moisture content because they can be fairly easily milled to the correct particle size. If plastic clays are used, they must, after drying, be brought to the appropriate grain size by granulation. Molding is then carried out by various stamping presses.

1.5.2. Machinery

Extrusion Molding. The most popular machine for extrusion molding is the screw or helical extruder (Fig. 8).

Figure 8. Screw extruder
a) Feed; b) Double shaft mixer; c) Vacuum chamber; d) Extrusion tube with screw; e) Die

The prepared mass is usually mixed first in a double trough mixer (b) with a sieve or annular discharge into the screw feed of the extruder (d). The molding head (e) forms an integral part of the die (f). The final pressed shape is formed in the die. Between the double trough mixer and the screw there is usually a vacuum chamber (c) in which the air is extracted from the shredded mass. This improves the binding and flow properties, and allows raw material of naturally poor molding properties to be molded. In addition, the formation of the extrudate by the die is improved by water or steam treatment.

Although the extrusion press has the advantages of continuous operation, high throughput, and varied forms, it has the disadvantage of texture formation, which can be aggravated by drying and firing. Lean mixtures also have a tendency to surface tearing and formation of "dragon's teeth" on the edges. The ring-shaped and S-shaped textures [32] caused by the action of the screw feeder cannot be wholly avoided. However, altering the granule characteristics (e.g., increasing as much as possible the proportion of easily fractured coarse granules) and modifying the screw, the die, and the molding head reduces the number of these textures so that the final product quality is not excessively affected.

Apart from the screw-fed extruder, the disk press (Europress, Fig. 9) is also used. In this press the screw is replaced by a roller feeder (c) resembling a V-belt pulley.

Figure 9. The Europress
a) Feed; b) Vacuum chamber; c) Roller; d) Die

The extrusion method makes possible the production of a wide range of surfaces on the molded shapes by the use of devices such as shaped rollers and brushes located near the die outlet. The surface of the extrudate may be coated with an aqueous sealant to avoid dry efflorescence.

Forming the extrudate with a suitably designed press and die (double die) allows the use of lower quality raw material for the molded shape with a surface layer of high-quality material a few millimeters thick.

Figure 10. Soft mud molding by hand

After leaving the die, the extrudate is carried by rollers or band conveyors to the cutting machinery, where it is cut into separate pieces. Each type of product requires its own *cutting system,* the most common being stretched steel wires. For roofing tiles, split clinker flags, and large blocks formed from soft material, knives are also used. With a ribbon harp (i.e., an array of parallel ribbon cutters) a long length of extrudate can be cut into a number of pieces in one cutting action. Even though this is quite slow, a high output may be obtained. For extrudates that are difficult to cut, e.g., stiff plastic masses or molded pieces with low green strength, a vibrating or saw action cutter is an improvement [18].

Soft Mud Molding. Before the brick industry became mechanized, the usual process was hand molding (Fig. 10), and this is still used to a small extent. A lump of soft plastic clay was beaten into a sanded mold, the excess material was removed by strickling, and the mold was inverted to release the product. These techniques are usually carried out with mass-production strickling machines.

Figure 11. Revolver press (schematic)
a) Conveyer belt from the clot press; b) Clots; c) Drum with lower molds; d) Plunger with the upper mold; e) Green body removal; f) Conveyer belt to the dryer

Press Molding. Products with complex shapes cannot be produced by extrusion; complex shapes are produced by stamping.

Articles such as special types of roofing tiles, wall and floor tiles with embossed surfaces, and face bricks with a "handmade" surface are made on a machine known as a *revolver press* (Fig. 11). The clots of clay are produced on a screw-fed extrusion press, either with or without a deairing stage. All stages of the process are automatic: placing the clots in the pressure mold, the various steps of the compression process, the trimming of the shaped pieces, their removal from the mold, and placement on a carrying frame or band conveyor.

For molding ridge tiles, ventilation bricks, and other special shapes, semi and fully auto-

matic turntable presses, as well as high lift revolver presses, are used.

The molds for stamping presses are still mainly made from high-strength plaster, sometimes bonded with plastics. Other mold materials used are lubricated cast iron, steel, molds with rubber sheeting, and metal molds with vulcanized rubber coating [1].

Dry press material is usually molded with *rotating table presses*, which are driven mechanically, hydraulically, or by a combination of the two. Mechanical or hydraulic toggle lever presses or friction presses are also used. These last two give the highest compression force.

With dry presses, the prepared, loose feed is loaded into the mold, where it occupies about twice the volume of the final molded piece. Exactly reproducible amounts of material must be charged so that the pieces are of constant size, and they must be compressed to the same extent, a task that can be difficult.

While the production of thin wall and floor tiles is relatively easy, thick pieces and pieces containing holes can present more problems. There are large frictional forces between the material and the die walls, and between the grains of the material itself, and these effects reduce the densification produced by the applied pressure. Steps can be taken to reduce these density differences, e.g., lowering the viscosity of the added water with flow-promoting agents such as lubricating gums (sulfite liquor, etc.). Another approach is to even out the differences by applying pressure from both sides.

An important method of preventing delamination is to deair the mixture. It can be improved by stepwise compaction of the grains by vibration processes and also by carrying out the compression in several stages [31].

The machines for the semidry pressing are fairly simple and require little maintenance. The pieces are preformed in molding boxes between two mechanically operated rams and then compacted again in a second shallower molding box (double pressing process).

1.6. Drying

The gauging water, which was needed to make a plastic mass, is removed during drying, the process that immediately follows forming. This drying is associated with marked shrinkage, which varies considerably in extent, generally ranging between 10 and 25 % by volume. When the green bricks are formed under conditions of flow, as in an extrusion press, the amount of shrinkage in the direction of the flow can be strikingly different from that in the perpendicular direction as a result of the orientation of the clay particles.

Drying occurs in two stages. In the first stage, during which ca. 1/3 – 2/3 of the water evaporates, depending on the material, nearly all the shrinkage takes place. A large proportion of the pore water and the water film around each solid particle evaporates, and the particles move closer together. In the second stage, the remaining water evaporates without appreciable shrinkage. The shrinkage can be measured as a function of the water removed with a Barelettograph, which requires only a small sample, and can be displayed as Bigot curves.

Incorrect drying of green bricks can produce distortion and cracking. The drying conditions are determined by both the type of brick and the material, which can vary with respect to mineral composition and grain-size distribution. Fine-grained, unmixed clay minerals, especially montmorillonite, can easily cause defects on drying, even in the case of small amounts. Products made from mudstone or shale, however, give few problems.

The most important factor affecting the drying properties of ceramic masses is the moisture diffusion through the mass. Reducing the sensitivity to drying, and hence drying times, therefore depends largely on improving moisture-diffusion properties. Suitable additives are nonclay inorganic materials, such as sand, slag, and brick dust, or organic fibrous materials, such as paper pulp or sawdust. In some cases, flocculating agents, such as calcium hydroxide, may be used, provided that they do not cause excessive deterioration in the molding properties [33]. The effects of nonclay minerals, and especially their particle size, on drying have been fully discussed [34].

On an industrial scale, brick products are generally dried with an air current, usually preheated. In times past bricks were almost exclusively dried in the open air or in large rooms above an oven. This is still true in developing countries, where land and labor are less scarce than capital. Modern drying equipment is almost

always capable of year-round operation, and the air temperature, moisture content, and throughput are controlled to give optimum product quality [35]. Open-air drying is no longer common.

The systems most frequently used are chamber dryers and tunnel dryers. The *chamber dryers,* which have single or double chambers, are periodically charged and discharged by means of fork lift trucks, with the green bricks stacked in several layers on grids or frames. The whole of the chamber contents are in contact with the drying air.

In the *tunnel dryer,* the feed material, which is carried by frame or pallet cars, is transported through a tunnel so that the drying air contacts the green bricks, either countercurrently or cocurrently. The principal advantage of a tunnel dryer is that it is a continuous process, thus providing a continuous feed to the next stage.

In both types of dryer, the air can be circulated horizontally and vertically, improving the drying effect [36]. Uniformity of drying, and therefore reduction of the time required, can be achieved with batch driers by judicious direction of the air stream [37]. One special characteristic is the rhythmic drying of the Rotomixair system, a system provided with wide currents of air or with longitudinal slit nozzles in the walls. The warm air flows intermittently for brief periods at a high velocity onto the material [1].

The evenness of drying of a charge or a chamber is affected considerably by the arrangement of the green bricks; this determines the permeability of the stack. As a general rule, drying time exceeds 24 h, because even green bricks with many holes are mainly dried by the stream of air flowing around the outside of the bricks [34], [38], [39].

So-called *rapid dryers* achieve crack-free drying of bricks containing holes in less than 6 h. A large number of air jets are used, whereby every single brick is subjected to an air stream over and through it. Whether or not a rapid dryer can be used in an individual case depends both on the shape and on the raw materials of the brick. Raw materials that are particularly sensitive to drying conditions are unsuitable for rapid dryers. The type and significance of the drying stress when air jets are used has been investigated [40].

The tunnel cars that contain the dried bricks are usually kept in heat-retaining tunnels before going into the kilns. Even if the raw materials contain a high proportion of swelling clay, this avoids most reabsorption of moisture from the atmosphere, and the consequent reduction in quality.

1.7. Firing

Brick products are fired predominantly in tunnel kilns because these require fewer personnel, are easily automated, and may be operated under uniform conditions. The stacking of the green brick on the cars is often done by stacking machines, not by hand. The earlier ring kilns (Fig. 12), zigzag kilns, and chamber-ring kilns are now used only rarely. For firing special products in small quantities and for influencing the firing colors of roofing tiles and clinker bricks by means of a reducing atmosphere, batch chamber kilns are occasionally used because they permit individual firing regimes.

The small arrows show the direction of motion

As a rule, bricks are direct-fired at peak temperatures of 900 – 1200 °C. The fuel can be gas, oil, or coal. Clinker bricks and slabs that should not come into contact with combustion products (which might affect the fired colors) are heated indirectly in tunnel kilns. High-quality wall and

floor tiles are occasionally fired in electrically heated kilns.

Bricks are usually heated by overhead firing, but sometimes also from the sides. The temperature distribution can be improved by high-velocity jet burners [1].

The energy requirement varies with the type of raw material, firing temperature, and kiln operating conditions. Ordinary bricks fired in a tunnel kiln require ca. 1 MJ/kg of fired material [39]. For the firing of insulating bricks, a considerable proportion of the heat energy is supplied by the combustible substances, e.g., sawdust, that are added to increase the porosity of the material [19], [20].

In order to fire at higher temperatures without causing distortion, e.g., to increase frost resistance or density of the fired body, roofing and wall tiles are fired inside boxes (saggars) to avoid deformation.

Firing Conditions. Because of the variety of raw material mixtures, as well as the sizes and shapes of the products, there are no universal firing conditions: each product needs its own firing regime [41].

The firing rate allowed at each stage of firing depends on the physical and chemical reactions of the raw materials: swelling, shrinkage, evaporation, combustion and decomposition processes, solid-state reactions, and formation of liquid phases, all depending on the thickness, size, and shape of the molded piece [42].

In the prefiring zone, with temperatures up to 300 °C, the rapid evaporation of the water can give rise to significant shrinkage, and consequent high distortion and crack formation, particularly with highly plastic masses containing large proportions of swelling clays.

Another critical temperature range lies between 450 and 650 °C. If the material contains quartz, this quartz can undergo large volume changes producing considerable internal stresses and therefore cracking.

For many materials, the rate at which the temperature may be increased above 600 °C is limited owing to a tendency to give *black cores,* the mottling of the outer surfaces or intumescence. The basic cause is the presence in the raw material of bituminous substances, plant remains, wood, coal, or combustible materials that have been added to increase porosity of the fired body or to economize on expensive fuels. The oxidation of these substances must be complete before the diffusion of gases is obstructed by vitrification of the material. This may be achieved by correct dwell times at set temperatures, which must be determined for each case [43].

Materials rich in limestone, such as marl clays, are useful for the manufacture of lightweight insulating bricks. However, significant shrinkage, causing cracks, can take place in the range of 800 – 900 °C because of silicate formation, especially in the case of large-sized bricks.

Cooling of brick products through 573 °C is a problem because at this temperature any free quartz changes from the high-temperature (β) to the low-temperature (α) form, with an accompanying reduction in volume (quartz transition). In products that require a high firing temperature, such as clinker bricks and floor tiles, some quartz can change to cristobalite, and this too gives rise to a contraction on cooling, in this case at 230 °C [44].

Figure 13 shows the typical firing curves for four different raw materials or product types.

Figure 13. Typical firing curves

Possibilities of controlling the emission of harmful substances, e.g., fluorine, during firing has been described [25], [45].

Expanded clay products occupy a special position. The wet-formed granules, which consist of pellets from a pan granulator, or fragments produced from shale by size reduction [46], are usually (ca. 90 %) fired in rotary kilns [1]. The feed material is heated to ca. 1150 °C in 30 – 45 min, with the firing controlled so that the outer skin is densely sintered before the gas begins to form in the interior, which causes the clay spheres to swell [12], [47].

1.8. Properties of the Fired Body

The fired body acquires the properties that render it suitable for its particular use mainly in the finishing burn, i.e., the time that the piece spends near the peak temperature. At the same time the density and strength of the body increase. In general, a longer residence time around the peak temperature improves product quality.

In the course of this sintering process, new mineral phases, mainly silicates, are formed as well as the glassy phases that bind the whole body together. The final properties that are desired are produced not only by the nature of the raw materials, the pretreatment, and composition but also by the firing process [48]. Porosity data, such as water absorption and strength, are used to assess the degree of sintering. The designation *sintered* denotes in practice that a definite, prescribed degree of densification and hardening has taken place.

Most brick products, such as inner-wall bricks, face bricks, roofing tiles, floor tiles, and drainage pipes, can be and even should be porous. For these products then, the required fired body strength, weather resistance, etc., can be attained before the sintering process is so advanced that softening and deformation occur as the result of the excessive formation of liquid phase.

Lightweight insulating bricks are made especially porous (body density of ca. 1.2 kg/dm^3) by incorporating substances that burn out during firing. Convenient raw materials are those that on firing produce a porous structure without additives, either because of their naturally high organic content (e.g., the overburden clays in the brown coal regions) or because of a high content of finely divided chalk. The relatively high porosity of fired products from chalk-containing raw materials (marl clays) is produced not only by the formation of CO_2 from calcium carbonate but also by the formation of calcium silicates, which prevent shrinkage at 900 – 1000 °C, sometimes even leading to expansion. The fired strengths of lightweight bricks made from clays rich in chalk are comparatively high; therefore, calcium carbonate as limestone or powdered chalk, is sometimes added to clays poor in calcium carbonate [21]. A further feature of chalk-containing bodies is that they must not be heated above 1060 °C, or they soften when calcium iron silicates suddenly melt.

Clinker products are manufactured from materials low in chalk. These materials, on account of the minerals and potential fluxes present, can withstand higher temperatures, reducing atmospheres, and prolonged dwell times at the peak firing temperature, becoming dense without deformation.

A special firing method, known as the Hydrite process, was developed in the former German Democratic Republic. This process involves firing the green bricks in indirectly heated kilns with maximum temperatures of ca. 780 °C. The dehydratation of the clay minerals produces a moist atmosphere, which irreversibly strengthens the fired brick, and, it is reported, giving higher compression strengths than by normal firing methods [49].

1.9. Coloration and Surface Effects

The color of fired brick products is determined mainly by the ratio of iron (III) oxide to aluminum oxide if the lime content is low. If the lime content is high, the color is determined mainly by the iron oxide/calcium oxide ratio [22]. Other raw material properties and firing methods play a role. Iron oxide usually gives red brick; lime tends to produce whitish-yellow brick. Incorporating a reducing stage in the high temperature and cooling zones produces varied shades, from yellow to green, blue, and gray black, in place of the usual red. This is mainly caused by the reduction of iron (III) to iron (II). If the reducing stage is prolonged and is continued until the product has completely cooled, small particles of carbon deposit to give a silver-gray appearance. This process is mostly used for the production of silver-gray roofing tiles. The use of raw materials containing adequate lime combined with a firing in a reducing atmosphere produces light colors.

Glazing and Engobing. A broader product range may be achieved by the use of a glaze coating on face bricks, wall and floor tiles, and similar items. These glazes are fused onto the already fired clay body; they consist of a mixture of silica sand, clay, alkali-metal and alkaline-earth metal oxides, lead and boron oxides, and

colored metallic oxides, such as CoO, Cr_2O_3, MnO_2, and Fe_2O_3.

Sometimes roofing tiles are also given a glaze. Usually, however, they are engobed with a porous layer, i.e., they are coated with a fine clay that gives a color on firing [50]. A shiny surface may be obtained if these coatings also contain lead silicates, alkali-metal compounds, etc., which melt at low temperatures (sintered engobing). Because glazing and sintered engobing both have the effect of densifying the surface it may be necessary to allow for the loss of moisture at the back of the brick to avoid frost damage [51], [52].

Solid Coloring. Occasionally, face bricks, tiles, and roofing tiles are colored throughout. Some examples of substances used are as follows:

Iron (III) oxide red
Manganese clays or manganese/iron ores brown
Mixtures of manganese/iron ores with chromium oxide black

To reduce the cost, the oxides used are ores or byproducts from other branches of industry, if possible [23]. The use of chromium oxide to produce a green color is economical only for high-value floor tiles.

Other methods of modifying the surface appearance of face bricks are treatment with rollers or brushes, removal of the surface skin, application of sand, surface treatment with combustible materials, and rock facing, i.e., mechanical removal of the outer surface of the fired brick.

1.10. Quality Control and Standardization

Continuous quality control of construction ceramics by recognized institutes is gaining in importance because over the years the quality requirements have increased considerably. In addition, most producers have their own quality control. The trend is to control the quality in-house and to rely on external testing only to monitor in-house quality control [13], [52].

In the *Federal Republic of Germany,* for example, the product requirements vary significantly with the end use but are standardized:

DIN 105		Mauerziegel (bricks and tiles)
	Part 1	Vollziegel, Hochlochziegel (facing and inner-wall brick)
	Part 2	Leichthochlochziegel (insulating brick)
	Part 3	Hochfeste Ziegel und Klinker (high-strength bricks and clinker)
	Part 4	Keramikklinker (ceramic clinker)
	Part 5	Leichtlanglochziegel und Leichtlanglochplatten (brick planks)
DIN 456		Dachziegel (roof tiles)
DIN 4 159		Ziegel für Decken- und Wandtafeln (wall and floor tiles)
DIN 4 160		Ziegel für Decken- und Wandtafeln (wall and floor tiles)
DIN 278		Tonhohlplatten und Hohlziegel (hollowbricks and tiles)
DIN 4 051		Kanalklinker (bricks for sewer construction)
DIN 1 057		Mauersteine für freistehende Schornsteine (bricks for freestanding stacks)
DIN 18 503		Pflasterklinker (paving clinker)
DIN 18 158		Bodenklinkerplatten (flooring clinker)
DIN 1 180		Dränrohre aus Ton (ceramic drain pipes)

European Standards. For several years now European standards (EN) have tended to replace the various national standards. For example, the quality control for split flags has been established as an European standard.

International Standards. The International Organization for Standardization (ISO) consists of representatives of national standardization organizations. Some non-European countries, e.g., Australia, Brazil, Canada, China, India, the former Soviet Union, and the United States, are also represented. The technical commission ISO/TC 179 has published "Materials Testing Methods and Requirements," which is important for ceramic products. In addition, the design

and construction of masony structures, both reinforced and non-reinforced, has been standardized. For developing countries, the *simple rules* have been made available.

Table 1 shows the standard lengths of bricks in several countries. The testing of ceramic raw materials and products is treated in more detail under → Ceramics, General Survey.

Table 1. Dimensions of standard bricks [10]

Country	Nomenclature	Dimensions, mm
France	most usual size	220 × 110 × 60
Germany, Federal Republic of	NF	240 × 115 × 71
United Kingdom	BS	210 × 102.5 × 65
United States	standard	203 × 95 × 57

1.11. Economic Aspects

In 1984, brick production in the Federal Republic of Germany was ca. 5×10^9 units (one unit equaling the standard format 240×115×71 mm). This production is equivalent to ca. 82 000 homes. In 1981, the fraction of brick wall construction in homes in the Federal Republic of Germany was 43 %. Sand-lime blocks and expanded-concrete blocks accounted for 34 % and 9 %, respectively, of wall construction. Ceramic tile is used for 22 % of the nonflat roof surface in the Federal Republic of Germany.

The number of brick producers in the Federal Republic of Germany decreased from ca. 1000 to ca. 320 over the 20-year period 1965 – 1985, the number of employees decreasing from 58 000 to 12 500. In the same period, the total production of bricks decreased by 22 %; that of roof tiles, by 32 %. In countries such as Belgium, France, Finland, Great Britain, Holland, and Sweden, the number of producers has decreased 75 – 80 % [13].

In 1982, a modern brick plant in the Federal Republic of Germany could produce ca. 120 000 units (ca. two homes) per day, i.e., 44×10^6 units per year at full capacity. The capital cost of such a plant was ca. 12.8×10^6 €in 1982. The sales were ca. 9.2×10^6 €, wages accounting for ca. 20 % of the sales.

Table 2 compares brick and roof tile production in several European countries [53].

Brick production is reported by number of bricks or by cubic meters of brick. Tile production is reported by number of tile or square meters of tile.

2. Stoneware

Stoneware is a traditional, clay-based ceramic with a densely sintered body, which is not translucent and has a conchoidal, stonelike fracture. Its external characteristics distinguish stoneware from other ceramic products: The densely sintered body is not absorbent and does not adhere to the moist tongue, which clearly differentiates stoneware from brick, grog (chamotte), and earthenware. Stoneware differs from porcelain mainly in the color of the body and often also in its coarser structure. Both unglazed stoneware and unglazed porcelain are impermeable to liquids. Light-colored stoneware is a type of whiteware (→ Whitewares).

The highly plastic nature of the clay mass for stoneware, the many possible methods of forming the shape, and the useful physical properties of the sintered body have led to variegated stoneware products during the course of the historical development. These include tableware, art objects, construction ceramics, and industrial ceramics. The division into coarse and fine ceramic products is based on the visible macrostructure of the body. Among the coarse ceramics are clinker, sewer pipes, and stable equipment; fine stoneware includes all densely fired ceramic products that are not porcelain.

2.1. History

The earliest stoneware is Chinese and dates back to the 1st and 3rd centuries A.D. All earlier ceramic products were porous, underfired pottery. The Chinese were the first to make a completely nonporous, brown stoneware. The Koreans and Japanese followed. In the 9th century A.D. the Chinese succeeded in producing white stoneware, representing the transition to porcelain. The famous China red glazes were the model for many European developments.

In Europe, where only porous earthenware had been produced in ancient times, there was a course of development similar to that in the

Table 2. Production of European countries in 1984

Country	Plants	Employees	Bricks, 10^6	Roof tiles, 10^6

Far East. Roman water pipes show that the ancient Romans were capable of manufacturing a fairly nonporous fired body. These high-quality pipes can be regarded as the first forerunners of industrial stoneware. With the fall of the Roman Empire, however, the art of stoneware manufacture was lost.

Stoneware reappeared in Middle Europe in the 11th century, favored by the availability of suitable clay, mainly in the Rhineland in the Eifel region (northwest of the Moselle) and the Westerwald (between the Lahn and Sieg rivers). Higher firing temperatures than was usual produced densely sintered bodies of great hardness and strength. At first these ceramics were unglazed. Stoneware manufacture was established in many other localities during the Middle Ages, e.g., Thuringia, Saxony, Bavaria, Silesia, and the Brandenburg March. The salt glazing process was discovered in the Rhineland in the 11th century.

In the main centers of stoneware manufacture in the 14th – 16th centuries, especially in the Raeren/Aachen region, the product was brown. Colored oxides, such as cobalt blue enamels and manganese dioxide allowed brown to violet colors to be obtained. The earliest manufacture of stoneware with a whitish to light-yellow body was in Siegburg. Typical Siegburg ware of ca. 1400 was decorated with detailed raised reliefs, which required a very fine, plastic clay body. Westerwald ware of the 16th century, especially from the Höhr-Grenzhausen region, may be recognized by its bluish-green body, incised patterns, and blue, violet, and brown decorations. Salt-glazed ware with red-brown colors was also common by this time. Very dark brown types of stoneware made their appearance in the early 17th century in the Creussen region (near Bayreuth). These were the precursors of Böttger ware (1708 – 1709), which led to the development of porcelain in Germany.

The Bunzlauer brown tableware of Silesia was not salt glazed, but had a clay glaze that was made from a mixture of several locally available earths. The establishment of technical colleges specializing in ceramics in Höhr-Grenzhausen (1879) and Bunzlau (1897) gave new impetus to the pottery industry and was a turning point in the industrial development of these regions.

Dense stoneware was first manufactured in England in the 17th century. In 1688, the Ehler brothers from Nuremberg founded a large pottery in Staffordshire; they also founded the stoneware industry in Lambeth, where their company became known as Doulton. From the 18th century onwards, English stoneware attained a worldwide reputation through the Wedgwood Company.

In the 19th century, industrial products became important. The manufacture of sewage pipes led the way. In Germany, materials were developed that were watertight, acid proof, abrasion resistant, and mechanically strong, and these replaced the porous pipes of English origin. In England, the chemical industry had attained importance during the first half of the 19th century, and thus it was here that Wedgwood and Doulton produced the first vessels, apparatus, and cooling coils from stoneware for chemical use.

In 1904 several German stoneware factories amalgamated, forming the Deutsche Ton- und Steinzeug-Werke AG in Charlottenburg.

In 1922 they combined with the company Deutsche Steinzeugwarenfabrik für Kanalisation und chemische Industrie in Friedrichsfeld (Baden). The two companies were world leaders in the field of stoneware for industrial chemical application.

Friedrichsfeld became famous for its Hoffmann stoneware body, a gas tight material that was relatively insensitive to temperature changes, and for another product, *Korundsteinzeug* (corundum stoneware), which had extremely high mechanical strength. The Deutsche Ton- und Steinzeugwerke AG provided a completely densified stoneware, *DTS-Sillimanite,* which was suitable for high-voltage insulators.

2.2. Raw Materials

The most important raw materials for all types of stoneware are the stoneware clays that contain kaolinite and fireclay (25 – 40 % total), together with other main components, illite (25 – 75 %), and sericite (→ Clays). Their relatively high alkali-metal content gives them good sintering properties. Montmorillonite can be present, although only in small amounts. The feldspar content is also small. The quartz content is 20 – 30 %, and the quartz is usually very finely divided. Quartz is beneficial in the formation of a good salt glaze. Stoneware clays in general have a very small particle size, and this is closely related to their most important properties. Between 60 and 95 % of the particles are less than 2 µm in size; consequently, stoneware clays are very plastic.

Typical stoneware clays with no added flux must be completely sintered when fired at Seger cones 4 a – 10 (1160 – 1300 °C). At the same time they must have as wide a sinter interval as possible: there must be at least five Seger cones between sintering point and melting point. Good stoneware clays sinter between 1200 and 1300 °C (Seger cones 6 a – 10) and have a cone "squat" temperature of 1580 – 1750 °C (Seger cones 26 –34). Therefore, there is excellent rigidity on firing up to the sintering point, in contrast to porcelain, and thus large articles can be manufactured. The sinter interval can be influenced by the type and amount of clay minerals or fluxes present in the clay. Illite contains alkali metals, and consequently promotes the widening of the sinter interval, but lime, magnesia, and iron oxide, especially iron oxide in a reducing atmosphere, act as fluxes and can significantly reduce it.

Depending on the iron oxide and titanium oxide content, and also on whether the kiln atmosphere is oxidizing or reducing, stoneware color is gray white, stone gray, blue gray, yellowish, or red to brown.

Typical stoneware clays can also be supplemented by plastic clays with a high quartz content, such as kaolin clays and kaolins, depending on the type of product and desired properties. However, there is no need to make use of kaolins for the purpose of achieving fine particle size with consequent high plasticity, these properties being more easily attained through the stoneware clays. Stoneware clays of various qualities (Table 3) are extracted in Germany, former Czechoslovakia (Wildstein), and England (Devon).

The amount of emphasis to be placed on clay purity depends on the type of ware. In any case, the clays must be free from coarse particles of sand and quartz, which could have a harmful effect on molding and drying. More important is the effect of these particles in producing stresses and structural damage caused by volume changes associated with quartz transitions during firing and cooling.

Good quality stoneware clays can also sometimes contain pyrites or other iron compounds such as marcasite, hematite, and siderite. These can give rise to melting defects at high firing temperatures unless they are finely ground and thoroughly mixed into the clay body. Calcium carbonate must not be present in stoneware clays because the very small particles of quicklime produced during firing slake subsequently and give rise to spalling.

Nonplastic, nonclay minerals include sand and grog, and some substances that also have a fluxing action, e.g., feldspar, feldspar sands, porphyry, and basalt. Fluxes differ from grog in that they must be finely divided or finely ground. Too much coarse material can cause porosity. The flux content must not be too high, or it can lead to distortion and formation of melting defects, blistering, and pitting.

Table 3. Chemical composition of stoneware clays, weight percent

2.3. Composition

Today a single stoneware clay is generally not used to make pottery, the exceptions being art and decorative tableware. Usually the desired clay properties are obtained by mixing several clays, sometimes with nonplastic fluxes. The proportions of the various clays and nonclay additions are chosen so that the plasticity and sintering properties of the clay body are suitable for the molding and firing process.

Figure 14. Effect of particle size of added grog (chamotte, chamotte : clay = 30 : 70) on strength of stoneware [59]

Clay bodies, normally quite plastic, are rendered less so by the addition of fired bodies ground to a definite particle size between 0.2 and 1.8 mm. This addition reduces drying and firing shrinkage and, therefore, sensitivity to the drying process. It also improves the rigidity of the mass during firing. Suitable additives are fired stoneware, fired porcelain, or grog produced by firing stoneware clay in a shaft furnace [58]. The amount, particle size, and particle shape of the added grog affect the fired density and strength of the body of the ware (Fig. 14).

Figure 15. Some ceramic products in the three-phase system clay – feldspar – quartz (% = wt %) [5]

The chemical composition of the clay body (see Ceramics, General Survey, Chap. 5.1., for

the Seger convention) lies within the limits given by
$RO \cdot 0.33 - 7.0\ Al_2O_3 \cdot 4.0 - 44\ SiO_2$
with RO varying between 0.7 (CaO + MgO + FeO) + 0.3 K_2O/Na_2O and 0.3 (CaO+MgO+FeO) +0.7 K_2O/Na_2O

Table 4 shows the chemical compositions of stoneware clay bodies. The stoneware bodies lie, along with porcelain bodies, in the mullite precipitation zone (Fig. 15).

2.4. Preparation

The preparation process brings the raw materials into a workable form, giving a clay body mixed to the correct consistency for molding [61]. Sometimes these processes begin in the clay pit, where harmful impurities, such as pyrite or limestone, are separated as far as possible. The actual preparation process comprises the following steps:

1) Breakdown of the plastic raw material
2) Breakdown, milling, and screening of the nonclay minerals
3) Proportioning
4) Mixing of the constituents

The breakdown of the clay must disperse the clay into its finest particles to produce good plastic properties.

The type and quality of the products determine the choice of the preparation process. As the structure of the fired body becomes finer and the specifications more demanding, the preparation process generally becomes more costly. Basically, there are four preparation processes, dry, semidry, hot, and wet, with the last the one used most often.

Dry Preparation [62]. All raw materials are broken down or milled in a dry state to the required fineness. The clay and nonclay materials may be milled separately or together. The clay minerals must sometimes be predried to a moisture content of 5 % to facilitate the size reduction process. The nonclay minerals are ground to a predetermined particle size before mixing.

The coarse size reduction of the clay (down to 10 – 50 mm diameter) is done by gyratory crushers; medium size reduction is by edge runner mills, roll crushers, or cutters; and for the finest product, double hammer mills, pin disk mills, ball mills, centrifugal roll mills, single roller ring mills, or clay disintegration mills are used. A particle size of 0.5 mm can be obtained. If still greater fineness is required, wet processing is necessary.

The grog (chamotte) often needed for stoneware manufacture must first be broken down roughly with jaw crushers prior to medium and fine grinding. Cross-beater mills and pin mills reduce the particle size to 0.5 – 3 mm. Swing hammer mills, centrifugal roll mills, single roller ring mills and Maxecon ring roll mills reduce the particle size below 1 mm. The sieved milled material can be used directly. The milled material may be classified so that the predetermined particle-size distribution gives the greatest packed density. Classification of the grog is carried out with vibration, resonance, and sonic sieves or with Mogensen sizers. The sieving equipment is generally fitted with magnetic separators (drum magnets), which remove the iron particles produced by abrasion in the milling equipment.

The various plastic and nonplastic constituents are measured by weight or volume [63]. Mixing is the final stage of the preparation process. The breaking down of the clay mix is further improved, and at the same time the finely powdered nonclay components are mixed in homogeneously. Continuous mixers may be used, e.g., single and double trough mixers or sieving mixers. The countercurrent intensive mixer, sometimes with a high-speed agitator, is a batch mixer.

The pure mixing stages can be followed by a souring process, in which the plasticity of the moist clay body is improved by prolonged storage. The clay – water reaction is promoted by the action of microorganisms such as algae and bacteria. This process can be considerably accelerated by raising the temperature, e.g., by steam heating. Improved plasticity can be achieved in a shorter time with souring towers.

Semidry and Moist Preparation. Another approach involves size reduction in which the clays are treated in the dry state or moist as mined. By later addition of the finely ground nonclay minerals and the water, a plastic mass is obtained with a water content of 15 – 25 %.

Hot Preparation. A temperature increase is produced by direct condensation of steam on the clay-body mixture, completely breaking down the clay and making molding easier to carry out. Drying time is also reduced. However, this method of preparation is used less frequently than the others.

Wet Preparation. The usual process for fine ceramics, wet preparation gives the most complete clay breakdown and finest milling, thus producing especially homogeneous mixtures. Milling and mixing take place in the presence of water. Nonclay minerals, such as feldspar and silica sand together with any hard or impure clays, are milled in rotating cylindrical mills with flint pebbles or balls made of porcelain, steatite, or aluminum oxide. Clays and kaolins sufficiently pure and finely divided not to require milling are slurried with water in blungers and then mixed with the wet-milled nonplastic materials. Both raw material streams are treated before mixing with magnets and vibration sieves to remove iron or remaining coarse impurities such as wood, coal, or coarse sand [64]. A filter press may be used to convert the slurry to a plastic mass with a water content of 20 – 25 %. Afterwards, grog or other material may be incorporated in a mixer. Alternatively, the filter cake may be dried, milled, and used in a dry press process or converted into a slip. The slurry can also be converted to granules in a spray dryer or simply to a plastic mass [65].

Table 5 sets out the preparation and molding processes used in the manufacture of various products [66].

2.5. Molding

Various molding methods are used to produce the shapes from prepared body [67], [68]. The usual processes are plastic molding, dry molding, semidry molding, and slip casting. The most important factor affecting the choice of process is the shape of the molded piece:

Small hollow bodies with uniform wall thickness by slip casting in a mold; larger ones by jollying

Bodies of any complicated shape with variable wall thickness by slip casting with a core; larger ones by molding

Small, symmetrical, thin-walled bodies by turning in plaster molds; larger ones by molding or extruding

Highly plastic, typical stoneware clay bodies are well suited for throwing, jollying, jiggering, or extruding, but unsuitable for slip casting, for which a leaner mass must be prepared. The method is often the most economical shaping method.

The most important forming process for continuous production of stoneware articles is *extrusion pressing* with a continuously operating vacuum screw press. The shaping process in the press, and especially the extrusion of the mass

Table 5. Preparation processes for various products [66]

* 2 = commonly used; 1 = restricted use; 0 = not used.

through the die, give rise to flow and the particles align, causing layering and "texturing" [69]. This effect can be reduced by adding grog and thus increasing particle size or by using clays with as large a proportion as possible of particles between 11 and 38 µm [70]. In the intermittent *piston press* the texturing is avoided, but the problem can occur at the die exit.

Moist or wet pressing of plastic masses is possible by using stamping presses, friction screw presses, and hydraulic presses. Heavy metal molds or porous plaster molds are filled with excess plastic mass. Surplus material becomes flowable during the pressing operation and comes away.

An important shaping method is *trimming,* in which preformed, extruded or slip-cast pieces are affixed to molded shapes or complicated apparatus.

Dry or semidry molding requires dry or nearly dry, crumbly or flowable granules with a moisture content of 5 – 8 %. Molding is done under high pressure by partly or wholly automatic hydraulic presses, e.g., friction screw presses, and turntable or toggle presses. Large blocks can be formed by stamping a crumbly mass containing ca. 6 % moisture through use of compressed-air stamping machines.

A slip with the lowest attainable water content is required for the slip-casting process. For this reason, 0.05 – 0.2 % electrolyte, based on dry clay [71], is added to produce a good, flowable slip. Sodium carbonate and/or silicate can be used. The viscosity can be adjusted to suit the wall thickness and corresponding standing time for a casting operation in a mold or around a core. The water content should, if possible, be no more then 3 – 6 % greater than that of the corresponding plastic mass, so that the drying process is not too prolonged. Stoneware clays are generally difficult to make into a liquid slip. They are slip cast in porous plaster molds with a water content of 20 – 26 %.

2.6. Drying

The water added to produce a moldable mass must be removed by drying before firing. The drying process must not distort the shape of the molded clay or crack it, which demands great care because the highly plastic stoneware clays require much water to make them moldable. The amount of shrinkage on drying is larger for the more plastic, finely divided clays containing larger amounts of water than for the less plastic clays.

In Bourry's diagram (Fig. 16), the volume change of the mass is shown during the course of drying. Although the rate of water loss remains fairly constant during the whole drying period, the volume reduction takes place mainly in the early stages, i.e., while the water film surrounding the particles is being lost. Pores are formed when the particles touch each other and cannot move any closer. Further water loss then merely increases the pore volume.

Figure 16. Bourry drying diagram for clay bodies [5]

The correlation between shrinkage on drying and water loss is shown in the Bigot curve, which has a characteristic form for each material (Fig. 17). The clay body, which is initially moldable, is brittle when the drying is complete. The drying operation must be carried out so that the changes in the state of the body take place evenly, and cause neither distortion nor cracking.

Figure 17. Bigot curve for drying a stoneware clay body

Inhomogeneities or texturing in the molded piece, sometimes produced by extrusion, causes drying stresses and raises the possibility of cracking.

The moist air drying process (→ Ceramics, General Survey) can be used for drying stoneware safely and economically [72].

After shrinkage is complete, usually when the residual water content has reached 6 – 8 %, drying can be safely speeded up by further increasing the temperature and reducing the relative humidity (Fig. 18). Total drying time and the course of each individual drying period must be established for each clay body and each type of product. The value of the lowest permissible residual moisture content should be set. The thicker the walls of the pieces and the finer the clay body, the lower this value must be, e.g., for stoneware pipes it must be < 1 %.

Figure 18. Moist air drying process for stoneware
φ = relative humidity, %ϑ_1 = dry-bulb chamber temperature, °Cϑ_2 = wet-bulb chamber temperature, °C

Depending on the type of product, batch dryers (floor dryers, chamber dryers, channel dryers) or continuous dryers (tunnel dryers) may be used [73].

2.7. Firing

The clay body or molded pieces after drying possess sufficient strength to undergo glazing, transportation, or setting in the kiln. During firing, processes take place within the body that are known collectively as sintering. Stoneware undergoes liquid sintering: a glassy phase is formed from the components of the body, which dissolves and binds together the other nonmelting components. The firing temperature must be chosen so that it is high enough to cause strengthening. However, it must not be so high that an excessive deformation occurs in addition to the normal uniform size reduction. The firing temperature of stoneware is 1100 – 1300 °C. The distinctive feature of the sintering of stoneware is that strengthening takes place while shape is retained.

The sintering properties of the stoneware body are dependent on a large number of factors: the chemical and mineralogical composition of the body; the condition of the raw materials,

e.g., particle size, standard of preparation, and packed density; firing temperature; time; and atmosphere. The porosity of the fired body is increased by loss of free water at the start of firing, combustion of organic components of the raw materials, subsequent splitting off of bonded water, breakdown of kaolinite, and decomposition of carbonates. It reaches its maximum at 900 °C. An oxidizing kiln atmosphere in this temperature region is advantageous because the remaining combustible components within the body are burned away. Above 900 °C the firing shrinkage begins, and porosity decreases. Increased flux content gives more of the glassy phase and thus a denser body (Fig. 19). This process takes place more readily when the clay body is finely milled, especially the fluxing component. Higher temperatures reduce the viscosity of the molten phase and cause the quartz to begin to dissolve, more readily if it is finely divided. Another factor promoting the sintering process is the packed density of the raw material. Every addition of grog reduces or delays sintering. All these relationships require that for each stoneware product the composition and fineness of the materials must be specified to suit the product.

Figure 19. Drying and firing shrinkage

The firing time is also important. There are two possible ways to achieve densely fired stoneware: either by terminating the firing process after reaching a high temperature, or by holding at a low temperature for a longer time, until the optimum degree of sintering is reached. The second method produces less distortion and eliminates blistering caused by overfiring.

Rigidity and strength development during firing are partially a consequence of reactions between the decomposition product of kaolinite, metakaolinite, and molten feldspar to produce mullite crystals, which strengthen the structure.

After the first (oxidative) firing stage, which produces the greatest porosity of the body, the final sintering can be carried out in either an oxidizing or a reducing atmosphere. The choice depends on the desired product. In a reducing atmosphere, i.e., firing with an oxygen deficiency, the reduction must take place between 900 and 1000 °C, so that it can still be effective before the pores in the interior of the body become closed by sintering. If the reduction starts at a lower temperature, below 800 – 850 °C, the Boudouard reaction can take place:

$$2\,CO \rightarrow CO_2 + C$$

and this can give carbonaceous deposits and blistering at higher temperatures. Reduction causes the conversion of Fe_2O_3 in the raw material to FeO, which reduces the viscosity of the molten phase and promotes sintering by acting as a flux.

The depth of the color of the stoneware body depends on the iron content. Oxidatively fired bodies are light yellow to brown; reductively fired bodies are light to dark-gray or blue-gray.

Firing is followed by cooling. The rate of cooling is determined by the type and size of products. The stoneware body, because of its composition after firing, still contains free quartz, and must be cooled slowly in the regions of the quartz transition (575 °C) and cristobalite change (200 – 240 °C).

The furnaces may be intermittent, e.g., chamber kilns, bogie hearth kilns, and top hat kilns [74], or continuous, e.g., tunnel and fast firing kilns [75]. The fuel may be coal, heavy oil, light oil, or gas.

Setting the ware in the kiln is an important operation. Shrinkage must be trouble-free, with no quality problems resulting from deformation. If necessary, the ware may be placed on some supporting material that shrinks at the same or a similar rate to the ware. Because the setting arrangement is often open, i.e. without saggars, fired refractory materials are often used, such as grog, cordierite, or silicon carbide, so that the ware may be equally distributed over the whole of the firing space.

To prevent ware softened through sintering from sticking to the supporting surface, the surface is covered with a suitable engobing, or it

may be covered with sand, quartz, or alumina-fiber paper.

2.8. Glazing

The traditional stoneware glaze is *salt glazing,* which is formed at the end of the firing. When the ware is already partly sintered, common salt is thrown onto the burning bed of coal and blown into the kiln by a blast of air, or sprayed into the kiln as an aqueous solution. The process is repeated several times during the firing. The salt is decomposed by the steam in the kiln atmosphere:

$$2\,NaCl + H_2O \rightarrow Na_2O + 2\,HCl$$

The Na_2O reacts with the SiO_2 and Al_2O_3 on the surface of the body and forms a fused coating, which on cooling solidifies to a glass.

This glaze formation requires temperatures $\geq 1100\,°C$ and a well-sintered body to avoid penetration of the glaze into a porous surface. It also requires that the body have a sufficiently high silica content. The final color is determined by the Fe_2O_3 content of the body and by the kiln atmosphere during firing and cooling. It can be brown to red-brown, light brown, or gray. Salt glazing is rarely used today because of changed kiln technology and the need to reduce environmental pollution.

When stoneware is to be glazed, it is coated with the glaze before firing by spraying, dipping, pouring, or brushing. The glaze may simply be a clay, or a feldspar, which may be colored with metallic oxides or colored bodies. The color range is limited owing to the high firing temperature, but an attractive range of effects is obtainable with the help of glazing technology: running glazes, craquelure glazes, matt glazes, ash glazes, crystal glazes, and shrinkage glazes.

2.9. Stoneware Products

2.9.1. Clinker Ware

The term clinker includes relatively thick slabs for floors and façades, wall and street surfacing, and clinker bricks, all having a sintered body and made from usually strongly colored clays (brown to reddish-black when fired). They are extremely hard, strong, and abrasion resistant. The method of manufacture is similar to that for bricks. For shaping, the extrusion press is usual for bricks, and the dry press is usual for slabs. Firing temperatures are 1150 – 1250 °C (see 446).

Standards for unglazed floor slabs are DIN 105 and Preliminary Standard DIN 18 158 (Dec. 1978).

2.9.2. Sewer Pipe

Stoneware is the classical material for pipes carrying domestic and industrial sewage. In the Federal Republic of Germany between 1980 and 1985, the consumption of stoneware pipes was ca. 300 000 – 350 000 t/a. This extensive use of stoneware is a tribute to outstanding properties: impermeability, strength, and corrosion and abrasion resistance.

The first sewer systems, which were based on clay ceramics, were constructed by 6000 B.C. in Turkey, although, of course, they were not completely impermeable (cf. Fig. 2). The first sewer system in Frankfurt am Main was built in 1200 A.D.; the first in England, in 1840. Hamburg's sewer system, begun in 1842, first used clinker pipes, then in 1875 stoneware, and in 1900 some concrete. The first factory for stoneware pipes was founded in Germany in 1852.

Preparation. The manufacture of stoneware pipe requires a plastic clay body made up of as many as five stoneware clays, so that any negative effects caused by variability of the properties of a single clay are averaged out. Clays low in chalk may be added, and other additives include basalt, sand, porphyry, and feldspar. In addition, 20 – 35 % powdered grog of grain size 0 – 2 mm may be added to reduce shrinkage, thus improving dimensional accuracy, reducing sensitivity to drying, and increasing rigidity of the product during firing [76]. The grog can be made from waste kiln furniture (support rings) of the same material, pottery fragments, and specially fired clay grog, e.g., bought-in material made in a shaft furnace. Fine-grained porphyry (0.8 mm) may also be used, either alone or with other additives.

A stoneware grog for sewer pipes has approximately the following size distribution:

<0.063 mm	3 %	0.2 – 0.5 mm	30 %
	5 %	0.5 – 1.0 mm	35 %
0.063 – 0.1 mm			
0.1 – 0.2 mm	12 %	>1.0 mm	15 %

Coarse grog should first be broken down in a jaw or hammer crusher to a size of ca. 150 mm. Final size reduction to ca. 10 mm is carried out in a Symons cone crusher or an impact and gyratory crusher. For uniform fine grinding to ≤ 3.5 mm, the Hazemag impact mill may be used or, more often, the Maxecon ring roll mill. The Mogensen vibratory sieve, which cleans itself by electrostatic repulsion, is the most suitable for separation into definite size ranges. With this equipment the mesh size of the top sieve should correspond to the size of the coarsest feed material.

The ingredients for the clay body could be 30 % extremely plastic stoneware clay, 22 % plastic stoneware clay, 10 % lean clay, 8 % loam, and 30 % grog.

The *clays* for stoneware pipes are not always usable in the raw state, but must undergo preparation. The quality requirements for stoneware, particularly in regard to strength, require the semidry or moist processes. The dry preparation process is hardly used.

In the *semidry* process [77], the various clays first arrive at a circular feeder, which measures out the individual clays in definite proportions. The moist clay mixture produced is then squeezed through the small sieve holes of a purifier, which removes gross contaminants such as coal, stones, and iron minerals. After passing through a roll crusher, the clay mixture is carried by band conveyor to a double trough mixer, where the grog is added. Finally it goes to a sieve mixer.

Molding. Stoneware pipes with sockets are formed by vacuum extrusion mainly by vertical screw presses. The water content of the stiff plastic mass is < 15 – 17 %. Although stiff clay bodies have a tendency to texturing, they may be used for manufacturing straight pipes up to 2 m in length and placed immediately on palettes or trucks where they keep their shape unsupported. They also dry more quickly. Of course, such pipes must be formed with heavy, powerful presses, e.g., 125 – 150 kW with a compression cylinder diameter of 0.45 m.

Figure 20. Screw press
a) Feed hopper; b) Prepress; c) Grid; d) Vacuum chamber; e) Press cylinder; f) Holder; g) Bell; h) Former; i) Die; j) Table

Both pipe and socket are formed by the extrusion press. In order to make the socket, a former, fixed to a vertically movable table, is brought up to the die exit before the start of the extrusion process and locked in position, where it exerts the necessary back-pressure against the thrust created by the screw press (Fig. 20). When the socket has been formed, the table is lowered to correspond to the rate of extrusion of the body of the pipe. Grooves are made in the plain end of the pipe, the socket end having been grooved during its formation. The pipe is then cut off and picked up by a gripping or suction device and placed on a palette or drying-chamber bogie. The density of the extruded article is influenced greatly by the form of the screw, i.e., the helix angle and the shape of the part nearest the mouth of the extruder.

The entire operation of the extrusion press, including groove making and cutting off and removing the finished pipe, is usually fully automatic [78]. So-called *top clay* pipes (Cremer +

Breuer, Frechen) constitute an interesting development in the automation of stoneware pipe manufacture. These pipes receive an inner glaze coating during the extrusion process and are immediately placed vertically on the tunnel kiln car. The setting ring, which is necessary to prevent deformation, is extruded at the same time in the form of an extra length of pipe. Firing in the tunnel kiln is carried out immediately after the drying process, and the usual transfer from drying cars to firing cars is thus omitted. *Top clay* pipes are unglazed on their outer surface.

The German Standard DIN 1230, Part 1, specifies that stoneware pipes be manufactured with a nominal diameter of 0.1 – 1.0 m and in lengths of 1.0, 1.25, 1.5, and 2.0 m. Larger diameters are available by special order only. Pipes with extra carrying capacity are specially strengthened (1.5 times normal wall thickness). The grooves formed in the pipes and sockets enable them to be joined tightly together.

In the United States, England, Belgium, and Holland, smaller diameter pipes are both extruded and dried horizontally. This technique is very popular in the United States, where the shale clays may be extruded in a rigid form and do not deform to oval.

Curved pipes are formed by using horizontal vacuum presses. After the socket has been formed, the emerging pipe is bent around a suitable guide. The process is automatic. The manufacture of branched pipes, at one time a matter of hand joining separate pipes, is now mechanized.

Drying. Chamber or, more often, tunnel dryers are generally used. The pipes, usually standing vertically, are dried in 24 – 48 h to < 1 % residual moisture by the moist air process. In tunnel dryers with so-called wandering cell drying, the pipes, standing on the grid floors of tunnel cars, pass through a drying tunnel with no blown or circulated air but with finned tubes at floor level carrying hot water. This hot water can be produced in the cooling zone of a tunnel kiln [79]. The heat rises from below through the vertical pipes and the moisture can escape through the roof of the tunnel, the permeability of which increases along the length of the tunnel.

Glazes and Glazing. Although the pipe body after firing is fully sintered and impervious, the surface is usually glazed, at least on the inside, to give a smooth, abrasion-resistant finish. The roughness factor K is thus decisively reduced, values between 0.02 and 0.15 mm being obtained. The earlier process of salt glazing of pipes in tunnel kilns is no longer carried out. Instead, the pipes are glazed by dipping in loam or feldspar glaze immediately after forming or drying [80]. With small- and medium-sized pipes the entire contents of a drying car can be glazed in one operation. The loam glaze consists of iron oxide-containing loam, marl, and flux-rich clay. Loam glazing is done at Seger cone 3 a – 12 (1140 – 1350 °C). Because the melting interval is only 3 – 4 Seger cones, the melting point is reduced by adding other fluxes such as pumice, basalt, calcite, dolomite, wollastonite, zinc oxide, feldspar, or nepheline syenite. The brown color produced by the loam or clay is itself insufficient, and is intensified with iron oxide and/or manganese dioxide.

The composition of a glaze for Seger cone 6a – 10 (1200 – 1300 °C) corresponds to:

0.4 CaO
0.25 MgO
0.25 K_2O
0.1 Na_2O
0.35 – 0.5 Al_2O_3
0.2 Fe_2O_3
3.5 – 4.5 SiO_2

A glaze composition for Seger cone 7 – 9 (1230 – 1280 °C) is 20 % glazing loam, 25 % Niederahr clay, 30 % feldspar K 40 (Mandt), 20 % dolomite, and 5 % calcite.

The glaze is ground in a well ball mill. This glaze must not have more than 5 – 10 % oversize on a standard 0.063 DIN 4188 sieve.

Firing. Chamber kilns and circular chamber kilns have now been replaced by bogie hearth kilns and tunnel kilns. Because of their greater economy of operation, tunnel kilns have generally taken over. Where chamber kilns are still in operation, they are fired with grid gas or oil. The heat consumption is 8 – 15 MJ/kg of ware. In contrast, large tunnel kilns specially constructed for stoneware pipe manufacture and having a width of 3 – 4 m, even 6 m (equal to the car width), require only 3 – 4 MJ per kilogram of ware. Tunnel kiln cars carrying 0.5 t/m^2 can give a daily output of 100 – 150 t. The kilns are 100 – 140 m in length and have a height that will ac-

Figure 21. Cremer's tunnel kiln system

commodate the pipes in a vertical position. Pipes 1 – 1.5 m long are fired with additional curved and branched pipes placed on top, but 2-m pipes are fired alone.

To prevent deformation and loss of the circular cross section, the pipes either are fired with setting rings which contract along with the pipes, or are made extra long but scored to enable easy separation after firing.

During firing there must be equalization of temperature over the whole cross section, from top to bottom, to avoid stresses in the pipes, and the same is true during cooling. However, cooling can be rapid – 400 °C/h – until the 800 – 700 °C region is reached, when cooling must be slowed, becoming as slow and steady as possible in the region between 600 and 500 °C, where the quartz transition takes place.

The cooling system of a reliable tunnel kiln consists of water-cooled tubes in the roof of the tunnel. The heated water can be cooled in a heat exchanger. The cooling of the kiln may be made to follow a predetermined cooling curve by automatic control of dampers under the cold-water tubes. Other cooling systems remove the heat by injecting air into the cooling zones and extracting it at a higher temperature from other locations.

A particularly well-established system for firing stoneware pipes is Cremer's tunnel kiln system, which uses side firing, a hot water cooling system, and continuous operation (Fig. 21).

The tunnel kiln often has a preceding predrying space, where the pipes are heated to ca. 150 °C. During the following heating period, all the remaining water, including absorbed water, is completely driven off. However, the rate of heating must be low enough to avoid spalling. Also, in this zone all organic components should

Figure 22. Reactions during firing

be burned off. The maximum firing rate is between 800 and 950 °C.

The firing zone must densify the body thoroughly. The vitrification, dissolution of quartz, and mullite formation must take place evenly over the entire cross section of the body.

Skillful arrangement of the burners, optimal air flow pattern, correct setting of the pipes on the kiln cars, and a suitable throughput time can ensure an even distribution of temperature across the whole tunnel cross section.

The processes taking place within the cooling zone determine the properties of the vitreous and quartz phases. As long as the vitreous phase still contains viscous components (the case down to ca. 750 °C), rapid cooling may be used, because the resulting stresses are relieved by plastic deformation. Immediately below this temperature, cooling must be very slow, especially in the re-

gion of the quartz transition at 573 °C, where a quiescent zone is necessary.

During firing, the reactions shown in Figure 22 take place.

Figure 23. Steckmuffe L

Figure 24. Steckmuffe K

Kaolinite, which has a layer structure, loses adsorbed water and water of crystallization to form metakaolinite, which then is converted to a spinel phase, a type of mullite, and finally, to primary mullite. During these reactions amorphous silica is liberated in several steps, and largely dissolves into the molten phase, but can also be changed to cristobalite. Illite gives up its adsorbed interlayer and crystallization water, and forms a molten phase at 920 °C and illite – mullite at 1000 – 1050 °C.

The chemical composition of fired stoneware materials can vary between the following limits:

60 – 70 %	SiO_2	0 – 1 %	CaO
20 – 30 %	Al_2O_3	0 – 1 %	MgO
1 – 4 %	Fe_2O_3	0.1 – 0.5 %	Na_2O
1 – 2 %	TiO_2	1.3 – 2.5 %	K_2O

However, the properties of the product depend less on the chemical analysis than on the mineralogical composition:

35 – 50 % vitreous phase 10 – 25 % quartz
15 – 30 % mullite 0 – 15 % cristobalite

If the proportion of vitreous phase falls below 25 %, the strength is low, while too much vitreous phase means a brittle product. The mechanical strength is also affected by the mullite, which is formed on firing, especially its particle size and the way in which it is embedded in the vitreous phase. Small crystals of mullite improve the properties of stoneware.

Figure 25. Compression strength testing of pipe sections

The density of stoneware sewer pipe is ca. 2.5 g/cm^3, the unfired density being 2.1 – 2.3 g/cm^3 and the total porosity (from texturing) between 2 and 15 %.

Jointing. The component parts of a stoneware sewer system (pipes, fittings, and special shapes) must be connected together by long-lasting, flexible, corrosion- and temperature-resistant, watertight joints. The seal must also resist tree roots and pressure from inside or outside the piping system. At one time common bituminous materials, which were melted and poured, and tarred rope, both of which were brought to the construction site, were used. This was a time-consuming task and did not always guarantee a leak-proof seal. These have been replaced by elastic seals that are tightly bonded to the pipe. The development of these prefabricated seals (by the Friedrichsfeld GmbH, Mannheim-Friedrichsfeld) was an important contribution to the continued existence of stoneware pipes in their competition with other piping materials. The socket seals were introduced into Germany under the names *Steckmuffe K* and *Steckmuffe L.*

Figure 26. Minimum compression strength – DIN and ASTM

Compression provides the seal. Pipes ≤0.2 m in diameter often need to be shortened and, therefore, the seal only comprises a solid ring of synthetic polyester resin cast within the socket (*Steckmuffe L*, Fig. 23). There is an additional seal consisting of a rubber ring.

Pipes over 0.2 m in diameter are sealed with *Steckmuffe K* (Fig. 24), consisting of a silica-filled solid polyester ring inside the socket and an elastic polyurethane ring cast onto the outside of the plain end.

The compression gives increased chemical resistance.

Standard Dimensions. The standard dimensions in Germany are given for pipes with sockets and for seals in DIN 1230, Part 1 (1979) and Part 2 (1979). Testing conditions and methods of control are also given.

Testing. The most important properties to be tested, apart from dimensions, are watertightness and corrosion resistance.

Strength. Tests are carried out on pipe sections 0.3 m in length (method A; Fig. 25) or on complete pipes. In order to allow for the large effect of the socket on the compression strength, the results must be calculated by method A:

$$F_{\mathrm{N}} = \frac{F_{\mathrm{B}} \cdot 1000}{l} \cdot 1.09 \left(1 - \frac{295}{l + 1440}\right)$$

F_{N} = compression strength, kN/m
F_{B} = breaking force of pipe section, kN
l = length of pipe section, mm

The minimum values of compression strength that pipes must withstand when tested are given in DIN 1230 (Fig. 26). The ASTM standards are also given in Figure 26. The BSI standards are shown in Figure 27.

Watertightness. To prevent pollution of the groundwater, the pipe seals of a sewer system must be watertight. This requirement is tested with an excess pressure (0.5 bar) inside the pipe, corresponding to the maximum pressure of water at 5 m depth. The test takes place over a 15 min period, after 1 h during which the pipe stands full of water at the test pressure. The water loss is measured and the loss factor calculated:

$$W_{15} = \frac{V_{15}}{\pi d_1 l_1}$$

W_{15} = water loss factor, L m^{-2} (15 min)$^{-1}$
V_{15} = water loss, L/(15 min)
d_1 = inside diameter, m
l_1 = length of piping, m

The water-loss factor must not exceed 0.07 L/m^2 of inner piping surface, and there must be no formation of droplets or wet areas.

Corrosion Resistance. According to DIN 1230, Part 1, stoneware pipes must not be corroded by wastewater, groundwater, or earth material, with the exception of hydrofluoric acid; DIN 51 102, Part 1, describes the determination of corrosion resistance using test pieces of prescribed dimensions that are subjected to the action of 70 % sulfuric acid for 6 h in a boiling water bath. The loss must not exceed 0.5 wt %.

Other required properties of pipes relate to roughness and abrasion resistance of inner surfaces. The testing of seals relates to their sealing properties, mechanical properties, chemical resistance, and temperature properties. The observance of all required properties is controlled either internally or by an outside body such as the Güteschutzgemeinschaft Steinzeugindustrie, Köln (Cologne). The internal supervision comprises daily or weekly testing of the quality

of the pipes and seals, dimensions, load-bearing capacity, and watertightness. The outside supervision involves carrying out the same tests twice a year without previous notice.

2.9.3. Stable Ware

Stable ware is made from the same material as sewer pipes. The molding processes are extrusion pressing and slip casting in plaster molds. The glazed stoneware articles such as mangers, troughs, drinking basins, and gutters fulfill all hygienic requirements. They may be cleaned either roughly or thoroughly, they are not attacked by acids or fermenting materials produced by decaying fodder, and they do not allow penetration by harmful fungi or yeasts.

Figure 27. Minimum compression strength – BSI

2.9.4. Products for the Chemical Industry

The stoneware in the chemical industry has a variety of uses. Its properties closely resemble those of the material used for sewer pipes, split flags, and floor tiles, and resemble industrial porcelain. Chemical stoneware may have a coarse or a fine structure, although the latter is more common. Products include containers, heating vessels, filters, columns, troughs, basins, working surfaces, pipes, valves, rollers, cyclones, extractor fans, pumps, and bleaching equipment. They must resist corrosion and, very often, mechanical and thermal stresses and abrasion.

Raw Materials. High-quality raw materials such as pure, uniform stoneware clays or standardized clays are offerd by suppliers, as well as kaolins, nonclay minerals, and fluxes. If quartz is necessary, it is added as ground silica sand or quartz powder. Feldspar acts as a flux and also makes the mix leaner. Potassium feldspar and potassium sodium feldspar are used.

Composition. The composition of the clay body for chemical stoneware depends on the molding method and the desired properties. The proportion of clays with more or less plasticity is occasionally supplemented by kaolin, which can improve firing properties but can at the same time lead to greater shrinkage. The addition of fired broken stoneware ground to a particle size of 0.2 – 1.2 mm, sintered clay grog, or porcelain fragments can have several useful effects, including a leaner clay body that reduces shrinkage on drying and firing, reduced drying sensitivity, and increased rigidity during firing.

Chemical stoneware consists mainly of SiO_2 (40 – 70 %) and Al_2O_3 (25 – 50 %). The 40 – 60 % vitreous phase contains crystalline components such as mullite, quartz, and/or corundum. The approximate makeup of the clay body is:

Component	Proportion, %
Stoneware clay, very plastic	20 – 35
Stoneware clay, plastic	10 – 15
Stoneware clay, lean	10 – 15
Kaolin	5 – 15
Feldspar	10 – 20
Stoneware grog (0.2 – 1.2 mm)	20 – 30

Special Bodies. The use of selected ingredients and especially crystalline materials that may be added or that are formed during firing, such as corundum, indialith (cordierite), and

β-eucryptite, which are embedded in the vitreous phase, encourages the development of special properties: mechanical strength, abrasion resistance, thermal conductivity, and resistance to thermal shock. The enrichment or presence of the following oxides tend to produce the physical properties stated:

- MgO Better resistance to alkalis and molten metals; with other suitable additives, formation of cordierite, which has low conductivity and hence good resistance to thermal shock
- SrO Properties intermediate between those of calcium and barium stoneware
- BaO Better resistance to alkalis and molten metals
- ZnO Better resistance to molten metals without affecting resistance to acids
- Al_2O_3 Better mechanical strength
- Cr_2O_3 Better alkali resistance without loss of acid resistance
- ZrO_2 Better acid resistance

Additions of corundum and argillaceous earth increase mechanical strength and hardness. The development of these bodies by the Deutsche Steinzeugwarenfabrik für Kanalisation und Chemische Industrie, Friedrichsfeld (Baden), dates back only to the early 1920s. In an improved form as ("corundum stoneware") they are used for mechanically strong acid-resistant pumps and apparatus.

A low coefficient of expansion is necessary to achieve good thermal shock resistance. This usually incurs penalties such as difficulties in manufacture or in attaining a good standard for other properties. Quartz or vitreous silica may be added as a grog grain owing to its low thermal expansion coefficient (0.55×10^{-6}) [81]; however, below a grain size of 0.4 mm, vitreous silica can be converted on firing to cristobalite, which has poor thermal shock properties. Also, quartz with a grain size over 0.8 mm can lower impermeability. Another problem with quartz additions to the body can be the formation of hairline cracks in the glaze, giving poor densification. By using steatite, talc, or magnesium carbonate in clay bodies and firing over 1150 °C, indialith (cordierite, $2\,MgO \cdot 2\,Al_2O_3 \cdot 5\,SiO_2$), can be formed. Such cordierite bodies have the low thermal expansion coefficient of $(1-2)\times10^{-6}$ between 20 and 100 °C. Furthermore, as a consequence of the small firing interval, production of densely sintered products with precise dimensions is difficult. Their use is still further restricted in the chemical industry by their poor acid resistance [82].

Products made from bodies containing barium oxide have lower expansion coefficients than mullitic stoneware, although not as low as those of cordierite stoneware. However, the products designed for good alkali resistance are better than mullitic stoneware in this respect [83].

The use of lithium-containing minerals and salts leads to the formation of β-eucryptite crystals, which have a very low and sometimes even negative thermal coefficient of expansion. The body has the extremely low expansion coefficient of $(0.6-2.0)\times10^{-6}$. The sinter interval is, however, small, and dimensionally accurate products are difficult to make. The thermal shock resistance of these products depends on size, shape, and wall thickness because of the anisotropy of the thermal expansion in different axial directions of the lithium aluminum silicate crystals.

Bodies with increased heat conductivity are obtained by the addition of silicon carbide, ferrosilicon, or silicon.

Preparation. The clay bodies are prepared by the semidry or the wet process (see page 21). The latter is preferred if superior mechanical or thermal properties are required or if the surface properties are especially important, e.g., for polished rollers, dense surfaces, or products whose glazed surface has aesthetic qualities.

Molding. Plastic molding and slip casting are the usual methods (see 2.5). The choice depends on type, shape, size, wall thickness, service conditions, and number of pieces to be produced. Rectangular vessels up to 1000 L in volume are extruded as box sections, and the side pieces are attached with slip. Larger containers are made entirely from vacuum-pressed plates (up to 2 m long) which are also attached with slip. Circular molded pieces up to a diameter of 1 m can likewise be extruded. Larger circular containers and vessels over 1000 L in volume are made by joining pre-extruded pieces in plaster molds, or they can be made on a rotating wheel in a plaster mold. For slip casting with plaster

shapes, the clay body is prepared with a water content of 22 – 26 % with the aid of electrolytes such as sodium carbonate, sodium silicate, or humic acid. The method of casting around a core is used most often.

Drying. See Chap. 2.6.

Glazing. See Chap. 2.8. A glazing process is frequently unnecessary, e.g., with polished ware, especially since the acid resistance and liquid impermeability are not produced by the glaze, but by the combination of densely sintered components.

Firing. See Chap. 2.7. The rate of heating is determined by the size and shape of the ware, the firing properties, the weight of the charge, and the kiln and burner construction.

The preconditions for an economical method of firing with rapid kiln turnaround, as well as consistent and improved quality, were provided by new circulatory and jet burners and corresponding kiln construction. The ware is now fired in gas-heated preprogrammed, rapid-firing kilns such as chamber kilns, bogie hearth kilns, and top hat kilns at Seger cone 8 – 10 (1250 – 1300 °C). One firing including cooling takes 4 – 5 days. Tunnel kilns are preferred for large batches of similar articles where the batch weight does not change continuously.

Finishing. Although shrinkage is taken into account at the molding stage, dimensional variations of up to ± 3 % are possible. For long production runs, tolerances of ± 0.5 % may be achieved. Demands for dimensions accurate within 0.01 mm may be met by machining, and this finishing process can also achieve a polished surface. The grinding medium can be a silicon carbide or often a diamond wheel. Diamond tools are suitable for drilling and cutting.

Properties. Chemical stoneware is resistant to corrosion by reactive media such as acids, solvents, and solutions of salts at all concentrations and temperatures, with the exception of hydrofluoric acid, which will damage ceramic materials even in trace amounts. Resistance to alkalis is strongly dependent on concentration and temperature (Fig. 28). If unglazed or surface ground bodies are to be corrosion resistant, they must be impermeable to liquids. Like all ceramics, chemical stoneware has high compression strength but low tensile strength. It is possible by structural means and by variation of the composition to produce special properties to suit the conditions in which pumps and apparatus operate in the chemical industry.

Figure 28. Solubility after 6 h of mullitic and indialith stoneware (1 g, grain size 0.25 – 0.60 mm) in sodium hydroxide solutions (DIN 51 103) [83]

Chemical stoneware is hard wearing, the hardness being 7 – 8 on the Mohs scale, equal to that of quartz or topaz. Corundum stoneware in which the corundum is very fine (< 50 µm), evenly distributed, and well bonded within the vitreous phase is especially hard wearing. Stoneware products are especially suitable for simultaneously corrosive and abrasive conditions [84]. In the "DKG-Werkstoffkennblätter für technische keramische Werkstoffe" ("German Ceramic Association Information Sheets on Industrial Ceramic Materials") [68] the areas of application, properties, and manufacturers of all industrial ceramic materials are described. Chemical stoneware materials are included under the headings DKG 150, DKG 152 and DKG 154 (see Table 6).

Use. Chemical stoneware can be used for pipes and shutoff devices, ventilation equipment [85], pumps, hydrocyclones, rollers, laboratory equipment (acid resistant basins and large working surfaces), and kitchen ceramics (sink units, working surfaces and cooking appliances).

Standard Specifications. Standard dimensions are given in DIN 7 000 – 7032 for pipes, valves, faucets, vessels etc. and in DIN 12 915

Table 6. Properties of chemical stoneware types [68]

Property	Symbol	Unit	DKG 150 chemical stoneware	DKG 152 chemical stoneware	DKG 154 corundum stoneware
Al_2O_3 content		wt %	30 – 35	25 – 35	40 – 50
Water absorbency (DIN 51 056, Section 5.2)	W_g	wt %	0 – 3	0 – 0.5	0 – 0.1
Green density	ϱ_R	kg/dm	2.2	2.3	2.5
Tensile strength	σ_{zB}	MPa	10 – 20	15 – 30	25 – 35
Compression strength	σ_{dB}	MPa	100 – 250	200 – 300	250 – 500
Transverse strength	σ_{bB}	MPa	30 – 40	45 – 65	50 – 90
Modulus of elasticity	E	kPa	50	55	60 – 70
Coefficient of linear expansion	α_t	$10^{-6}\ K^{-1}$			
20 – 100 °C			4	4 – 5	5
20 – 600 °C			4 – 5	4 – 5	5 – 5.5
Acid resistance (relative weight loss, DIN 51 102, Sheet 2)		wt %	0.5 – 0.8	0.3 – 0.6	0.2 – 0.6

and 12 916 for laboratory basins and large working surfaces in chemical stoneware, this information being also available in Werkstoffblatt (Materials Sheet) 71 of the DECHEMA-Werkstofftabelle (Materials Register). Special standard specifications govern the testing of resistance to acids and alkalis (DIN 51 102, Part 2, and 51 103).

2.9.5. White Chemical Stoneware

The special group of white chemical stoneware arose from a requirement for a material with the same properties as the brown salt-glazed stoneware but with a light-colored porcelain-like body. The *raw materials* are clay bodies of similar composition to the usual stoneware, but with clays as pure as possible, which fire to a light color. To achieve this aim, iron-free raw materials are used and prepared by the wet method. Molding processes must take into account the low plasticity of the clay body. Feldspar glazes opacified with tin or zircon are used for glazing. Flow properties and adherence (for dipping, brushing, or spraying) may be improved with organic thickeners, e.g., carboxymethylcellulose (Tylose from Kalle of Wiesbaden or Relatin from Henkel of Düsseldorf) [86]. The following Seger formula (soft porcelain) is suitable:

0.5 CaO
0.1 MgO
0.15 ZnO
0.25 K_2O
0.3 Al_2O_3
2.8 SiO_2

The ingredients are:

44 % Norwegian feldspar	12 % calcite
6 % dolomite	4 % kaolin
4 % zinc oxide	30 % silica flour

White stoneware is fired only in pure, oxidizing atmospheres at Seger cone 8 – 10 (1250 – 1300 °C) in chamber or bogie hearth kilns heated with gas or light oil.

It is only a small step from white stoneware to so-called industrial porcelain, which is produced from fine clay bodies without added grog, is fired at Seger cone 8 – 12, and resembles soft porcelain bodies. It is made into industrial articles such as kettles, columns, pipes, rollers, valves, and faucets whose outstanding property is mechanical strength. The clay bodies may be fired in oxidizing or reducing conditions.

2.9.6. Tiles and Slabs

Ceramic tiles of all kinds will soon be subject to a unified European standard laid down by the Comité Européen de Normalisation (CEN), and stoneware wall and floor coverings occupy an important place in this. According to the proposed CEN definition, tiles are regarded as building materials when they are used to cover floors and walls both indoors and outdoors, irrespective of size or shape. They can be unglazed, glazed, or engobed [87]. In the future these products will be classified according to molding method and water absorption. The following

will thus count as stoneware: split clinker flags, extruded slabs, and dry pressed or slip-cast tiles, all with a water absorption of not more than 3 %.

Split Clinker Flags. The name comes from the method of manufacture. Two slabs that are weakly bonded together back to back are split apart after firing. The parting line is formed by knives set in the die of an extrusion press. This makes a scratch on the core. The single slabs have grooves with a dovetail shape in the direction of extrusion on the back, and these give a good bond when mortar is applied. Split clinker flags are used as frost-resistant building components for indoor and outdoor wall coverings and for swimming pools. They are manufactured in various sizes, shapes, and colors, both glazed and unglazed.

The body corresponds to typical stoneware compositions with mixtures of stoneware clays of various plasticities:

30 – 50 % stoneware clays of varying plasticity
10 – 25 % grog or powdered fired body
10 – 20 % silica flour
5 – 20 % feldspar
0 – 5 % talc

The required grain size of the grog or the powdered fired body depends on the desired surface structure. Fine, smooth surfaces require a grog milled to a particle size $< 60\,\mu m$. For a rustic effect, which at the present time accounts for 60 – 65 % of production, the grog can be ≤ 1 mm.

For open-air swimming pools a grade made with fine grog is usually used. The raw materials are often prepared in high-output installations by the dry and semidry processes. The vacuum extrusion molding process is automated, including the cutting and setting of drying racks. The slabs are stacked on their longitudinal edges in chamber dryers with good air circulation or dried in continuous dryers with adjustable lateral air injection. Then they are carried on conveyor belts through one or more automatic glazing stages, where they are coated with feldspar glazes by spraying, pouring, or hosing. After this, they are automatically set onto kiln cars and fired at Seger cone 6 a – 10 (1200 – 1300 °C) in an oxidizing atmosphere in a tunnel kiln, where the energy consumption is 2.7 – 3.0 MJ/kg. The final processes of splitting, sorting, and packing are all automated.

Quality requirements and testing procedures are summarized in DIN 18 166. The following important individual test methods are planned: water absorption (DIN 51 056), transverse strength (DIN 51 090), acid and alkali resistance of the glaze (DIN 51 092) and acid and alkali resistance of the unglazed slabs (DIN 51 091).

Figure 29. Schematic diagram of electrophoretic formation of clay body sheets
a) Outlet for reusable excess slip; b) Clay body particles deposited by electrophoresis; c) Counterelectrode (cathode); d) Inlet for slip; e) Zinc anode; f) Two-layer sheet of clay body; g) Belt conveyor

Single Extruded Slabs. These are also formed by a vacuum extrusion press and may be given their exact rectangular or square shape by a later punch press operation. Sometimes this can also include a dry glazing step to give a rustic effect. Slabs are also produced in a punch press by a process still being developed. Continuous sheets of clay body are produced from a slip by an electrophoretic process using the "Elephant" machine of the firm Karl Händle & Söhne, Mühlacker (Fig. 29). The desired shapes and sizes (from small mosaic tiles up to 60 × 60 cm slabs) can be punched out from this by means of the Lingl punch press [88]. The output of clay body sheet is 60 – 100 m^2/h, with a thickness of only 4 – 6 mm.

Large Slabs. Since the early 1970s, large Keraion slabs have been manufactured in stoneware by the company Buchtal, Keramische Betriebe, Schwarzenfeld. The largest size produced is 1.25 × 1.60 m and normal sizes are 0.6 × 0.6 m and 0.3 × 0.6 m. All the slabs are 8 mm thick, weighing only 18 kg/m^2. Again,

molding is done with an extrusion press, but the extruded slabs must be passed between rollers until the desired size and thickness are obtained. Keraion slabs may be used for covering walls, floors, or ceilings, and can be used for interiors or façades.

Test methods suitable for Keraion slabs are given in DIN 18 166, and the properties meet or exceed the specifications: compression strength ca. 200 N/mm^2, transverse strength 30 – 35 N/mm^2 if the glazed surface is under compression and 20 – 22.5 N/mm^2 if it is under tension, modulus of elasticity 65 000 N/mm^2.

Dry-Pressed Tiles and Slabs. The European tile industry underwent a change of direction in the 1950s after far-reaching developmental work in Italy and Spain. Completely automated factories came into being, with a completely new concept. Mass production of this kind requires that the greatest importance be attached to consistency and standardization of raw materials. These are stored in large silos with sophisticated weighing equipment. The preparation method often depends on the particular types of raw material available. Thus, the wet process with spray drying may be used or the semidry or dry process. The product is a flowable granular clay body with 5 – 8 % moisture, suitable for dry pressing in high-power presses. Grain-size distribution and an even moisture distribution are vital for defect-free molded pieces. The usual automatic presses used are hydraulic presses, friction screw presses, or combinations thereof. They operate at a maximum pressure of 500 t and 15 – 18 strokes/min, up to four 15×15 cm tiles being produced per stroke. All subsequent operations of removal, transport, drying, glazing, and setting in the kiln are completely automatic. Drying occurs in a rocking dryer.

Glazing is by various means, e.g., squirting, dripping, spraying, sheepskin-covered rollers, brushing equipment, etc. Dry glazes may be applied either evenly or unevenly to produce special effects. Flowable spray-dried glaze can be applied during the pressing operation by feeding it onto the clay body in the mold from a separate push feeder and, after the bottom molding plate has been lowered slightly, pressing the glaze onto the molded piece. Another possibility is to apply the glaze preprepared in the form of sheets or foil.

For firing in tunnel kilns there is automatic equipment to load and unload saggars stacked one on top of another. Flat flame kilns for so-called fast firing are energy saving and highly automated. The throughput times are up to 60 min. The output of a 60-m-long flatflame kiln, for shapes 200×300×10 mm, with throughput times of 65 – 100 min and firing temperatures of 1180 – 1200 °C, is said to be 1200 –1500 m^2/d with a heat consumption of 2.5 –2.9 MJ/kg. Flatflame kilns are designed as single and multilayer roller kilns and as bogie kilns. In the latter, the charge is placed on solid supports of aluminum oxide, Pythagoras body, or special steel fixed to the flat upper surface of the kiln car.

The Standard Specification DIN 18 155 (March 1976) applies to stoneware tiles; in Part 1, the concept and constitution of fine ceramic tiles are defined and their applications are explained. Part 2 gives shapes and measurements; Part 4, quality requirements and testing. Stoneware tiles, whether glazed or unglazed, must have a transverse strength of at least 25 N/mm^2 (for test method see DIN 51 090). Test methods for thermal shock resistance are given in DIN 51 090, and for household chemicals, acids, and alkalis they are given in DIN 51 092.

1. Introduction

Millions of people throughout the world today use a variety of contraceptive methods to regulate human fertility. These include chemical methods, such as oral contraceptives, vaginal contraceptives, injectable/implantable contraceptives, and contragestational agents. They also include other methods such as intrauterine devices, intravaginal barrier methods; male and female condoms, surgical sterilization, induced abortion, and natural family planning. It is generally accepted that none of these methods represents an ideal method of fertility regulation [1–3] for everyone. Each has its own advantages and disadvantages. A comprehensive listing of contraceptive products can be found in [4].

2. Natural Methods

2.1. Periodic Methods

Abstinence from sexual intercourse during the fertile period of the menstrual cycle with the intent of avoiding conception is reviewed in [5]. Knaus first found, in 1929, that the fertile period in women occurs before menstruation [6]. A year later Ogino in Japan independently confirmed this finding [7]. From their studies, Knaus and Ogino developed formulas to determine the fertile and infertile days of a woman's menstrual cycle. At about the same time, van de Velde found a link between ovulation and a cyclic shift in basal body temperature [8], which can be used to determine the time of ovulation. These studies gave women the possibility of calculating retrospectively the time at which they ovulate and of abstaining from intercourse during their fertile period.

The primary difficulty with utilizing periodic abstinence (rhythm method) to prevent conception lies in the month-to-month variation in the time of ovulation. Whereas the ovum can only be fertilized during the first 12 – 24 h after its release from the ovary, sperm remain viable in the female reproductive tract for 5 – 7 d and perhaps longer. Thus, intercourse several days prior to ovulation can result in pregnancy.

More recent findings may better identify the fertile period. Changes in the quality and quantity of cervical mucus occurring 5 – 6 d prior to the mid-cycle surge of luteinizing hormone (LH), which initiates ovulation, can be used to predict the fertile period. However, it is sometimes difficult to recognize the changes in mucus. In addition, colorimetric enzyme immunoassays have been developed for the measurement of LH in urine. Since LH is rapidly excreted, the increase in urine LH levels can be used to predict impending ovulation. Recent studies suggest that urine LH testing every evening is a more reliable method of predicting ovulation within the ensuing 48 h [9]. However, despite these advances and others which will be made in the future, one must always remember the life span of sperm in the female reproductive

10.1002/14356007.a07_461

tract and be cautious in predicting how useful the method will be in identifying the onset of the fertile period. Research on other methods of consistently and accurately predicting ovulation are in progress.

2.2. Breast Feeding

In many societies, it is commonly believed that women who are breast-feeding are incapable of becoming pregnant. Suckling leads to a release of the hormone prolactin, which in turn suppresses the release of estrogen from the ovary and luteinizing hormone (LH) from the pituitary gland. The suppression of these hormones results in the inhibition of ovulation.

However, although breast-feeding does affect ovulation, it is generally accepted that the duration of lactational amenorrhea and infertility is variable [10] and that maximum birth spacing is achieved only when a mother is "fully" or nearly fully breast-feeding. The consensus of researchers in the area of lactational infertility appears to be that, if used in this way, full breast-feeding can provide as high as 98 % protection from pregnancy but not beyond the first six months [11]. Thus, breast-feeding is not reliable generally as the sole method of fertility regulation.

3. Barrier Methods

3.1. Chemical Vaginal Contraceptives

Vaginal contraception dates back as far as 1850 B.C., when written instructions for vaginal contraceptives appeared in Egyptian papyri. Vaginal contraceptives are among the simplest and most widely utilized forms of birth control available today. Major advancements in vaginal contraceptives have been made by conducting research into sperm motility and by the development of spermicidal assays [12] which could be used to search for spermicidal agents for inclusion in vaginal contraceptives.

In 1855, KOLLIKER reported on the effects of chemical agents on sperm motility [13], prompting the first studies in vaginal contraceptive research. In 1880, RENDELL produced the first commercial vaginal contraceptive: a suppository of cocoa butter containing the spermicide quinine sulfate. Vaginal preparations containing other agents toxic to sperm, such as boric acid, tannic acid, or mercuric dichloride rapidly proliferated. Due to their lower spermicidal potency or potential toxicity, only a few of these are still in use.

In 1932, BAKER [14] provided the basis for in vitro spermicidal assays for the evaluation of new spermicidal agents. In the late 1930s Ortho Research Laboratories developed the Sander Cramer test [15], which has been widely used since then to find new spermicidal agents and to compare spermicidal formulations. In the 1940s, the first surface active spermicidal agents, octoxynol [*9002-93-1*], 4-diisobutylphenoxypolyethoxy-ethanol, trade name Triton X-100, and nonoxynol-9 [*26027-38-3*], 7-nonylphenoxypolyethoxyethanol, trade name Triton N, were discovered and developed at Ortho Research Laboratories [16]. These two agents rapidly became the principal active ingredients in vaginal contraceptives worldwide. A third surfactant spermicidal agent, menfegol [*57821-32-6*], 4-menthanylphenylpolyoxyethylene(8,8)ether, was discovered and developed by Eisai in the late 1960s [17].

Nonoxynol-9

Triton X-100

Menfegol

The prevalence of HIV infection and other sexually transmitted diseases (STD) have led to focused research efforts to develop new spermicidal agents which also have antimicrobial activity [18].

The formulations used in vaginal contraceptives consist of a relatively inert base material, which to some extent blocks the passage of sperm and also serves as a carrier for the chemically active spermicide. In the last several decades, it has been recognized that the inert formulation that contains and delivers the spermicide can affect the efficacy of vaginal contraceptives [19], [20]. As a result, physical properties of vaginal contraceptive formulations have been improved to deliver the spermicide more effectively and/or to enhance consumer compliance. Formulations include jellies, creams, suppositories, films, aerosol foams, and foaming tablets.

The major advantages of vaginal contraceptives are simplicity and safety. In addition, they do not require medical supervision. Previously considered to be relatively ineffective, it has since been shown that vaginal contraceptives can, but only if consistently used properly, be effective [20].

3.2. Physical Barriers

Various physical barrier devices are manufactured for use by men and women to regulate fertility. These include condoms, diaphragms, and cervical caps, and they may be used in conjunction with vaginal contraceptives.

Diaphragms are shallow rubber cups with a flexible metal rim that are placed over the cervix. They act both as a mechanical barrier to sperm and as a receptacle for a spermicidal agent. The major mechanism of action is believed to be spermicidal rather than barrier. To be effective, the diaphragm must fit, be inserted properly, and remain in place sufficiently long for the spermicide to act [21].

Cervical caps are available in Europe, although they have not yet been approved for use in the United States or Japan. Cervical caps are deeper and smaller in diameter than diaphragms, and they are often made of rigid plastics, such as lucite; others are made of rubber. They cover only the cervix and are held in place by suction. Cervical caps are believed to have about the same degree of effectiveness as the diaphragm.

In May, 1993, the FDA approved the first female condom, Reality, for nonprescription sale in the United States. The same device had previously been available in Europe and Canada [22]. The Reality female condom is a thin, soft, loose-fitting polyurethane sheath with two flexible rings. The female condom provides women with an opportunity to help prevent unintended pregnancy and STDs without participation of the male partner; the use of a female condom is entirely under female control [22].

Another type of barrier contraceptive device is the vaginal contraceptive sponge. Clinicians do not appear to be enthusiastic about this method, however. Studies show that the failure rate for the contraceptive sponge in parous women is higher than the failure rate for the diaphragm. A U.S. study of the contraceptive sponge found a first-year failure rate of 13.9 % in nulliparous users and a 28.3 % first-year failure rate in parous users. Other disadvantages of the method include allergic reactions in a small percentage of women and a slightly increased risk of nonmenstrual toxic shock syndrome (TSS). Compared with other over-the-counter methods, the sponge is expensive [23].

The male barrier contraceptive device is known as the condom and is widely available in most countries. The condom is a rubber sheath, sometimes packaged with a lubricant and spermicide, which serves as a cover for the penis and a receptacle for semen. The method is very effective if the condom is properly used. Usage appears to be increasing in conjunction with other methods of contraception for prevention of HIV or other STDs. By rough estimate, condoms may have been used in more than 13 billion acts of sexual intercourse that risked unwanted pregnancy, HIV, and/or other STDs [24].

4. Hormonal Methods

4.1. Oral Contraception

Combination oral contraceptives, first introduced in the early 1960s, contain a synthetic progestogen and a synthetic estrogen. There are over 60 million users of this method in the world today, and almost 150 million women have used oral contraceptives sometime during their reproductive lives [25]. The American College of Obstetrics and Gynecologists (ACOG) has published a Technical Bulletin on hormonal contraception [26]. According to ACOG, in addition to being extremely effective as a contraceptive

agent, the use of oral contraceptives is associated with a variety of health and noncontraceptive benefits, including quality of life benefits and protection from certain gynecological malignancies.

The idea that hormonal control of ovulation might be practical first appeared in 1921 in the work of HABERLANDT, who showed that extracts of the corpus luteum could make mice and rabbits infertile [27]. During the next 20 years, the female steroidal sex hormones progesterone and β-estradiol were isolated, identified, and synthesized. Unfortunately, evaluation of their clinical efficacy was severely restricted by insufficient quantities of compounds for testing. By 1943, MARKER had developed a method for synthesizing progesterone and other steroid derivatives from diosgenin, a naturally occurring steroid present in a species of Dioscorea. MARKER's studies led to the synthesis of larger quantities of these and other steroids which could be evaluated clinically for their effects on fertility regulation. For further information on hormones, see → Hormones.

Progesterone [*57-83-0*] is a natural female hormone which affects ovulation; it is largely deactivated when given orally. However, anelimination at C-19 of progesterone results in a compound that is orally active. Similarly, structural modification of steroids from other hormone classes, such as the elimination at C-19 from testosterone, results in compounds (progestogens) which have progesterone-like effects (they induce secretory changes in estrogen-primed endometrium; induce the formation of thick, viscous cervical mucus; and suppress the release of luteinizing hormone and ultimately ovulation) [28]. In 1951, DJERASSI at Syntex and COULTIN at Searle in the United States produced the substituted synthetic progestogens, norethisterone [*68-22-4*] (called norethindrone in the United States) and norethynordrel [*68-23-5*], which are still utilized in oral contraceptives today.

Other progestogens which were subsequently synthesized include lynestrenol [*52-76-7*], chlormadinoneacetate [*302-22-7*], medroxyprogesterone acetate [*71-58-9*], ethynodiol diacetate [*287-76-7*], levonorgestrel [*6533-00-2*], desogestrel [*54024-22-5*], norgestimate [*35189-28-7*], and gestodene [*60282-87-3*].

Norethindrone

Norethynodrel

Lynetrenol

Ethynodiol diacetate

Norgestrel (levonogrestrel)

The first clinical study of an oral contraceptive began with a pill which investigators believed contained only the progestogen norethynodrel. Early clinical data demonstrated that this preparation inhibited ovulation. In subsequent studies with newly synthesized batches of the progestogen, ovulation was inhibited, but significant intermenstrual vaginal bleeding also occurred. It was then discovered that the original batch of norethynodrel, which gave better menstrual cycle control, was contaminated with an estrogen, mestranol. This led to the subse-

quent discovery that addition of estrogen to pure progestogen not only controlled intermenstrual bleeding but also increased antiovulatory efficacy. This led to the controlled inclusion of estrogen in future combination oral contraceptives [29].

Most oral contraceptives today are combinations of a synthetic estrogen and a progestational agent (progestogen). Estrogens are produced in the ovary and are important in preventing pregnancy; they work in conjunction with the progestogen to suppress ovulation. This combination also provides several ancillary contraceptive mechanisms by interfering with fertilization and implantation processes should ovulation occur [25].

The second- or third-generation oral contraceptives available today are much safer than the original products. The original combination products, introduced into clinical use in the 1960s, contained relatively high doses of estrogen and progestogen to ensure maximum contraceptive effectiveness in the absence of dose-ranging studies. The development of oral contraceptives preceded the introduction of liberal abortion laws in many countries. The knowledge that a pregnancy could not be terminated if women became pregnant in a clinical study prevented clinicians in those early studies from titrating the dose of hormone needed to prevent pregnancy down to the lowest effective dose. Epidemiological studies during the 1960s and 1970s indicated that oral contraceptive usage at that time was associated with an increased risk of thromboembolic disease. These cardiovascular complications were associated with the relatively high doses of estrogen used in original oral contraceptives, especially in women who smoke. Those findings led to the development of low-estrogen dose combination oral contraceptives (see Table 1, above).

For example, early oral contraception formulations contained up to 100 – 150 µg of estrogen. By the early 1990s, the majority of oral contraceptives contained only 30 or 35 µg of estrogen. These low-dose products are commonly referred to as second-generation oral contraceptives, and have almost totally replaced the original high-estrogen oral contraceptives. Numerous review articles and reports on cohort studies describing the use of oral contraceptives and the incidence of side effects are available [30–44].

As pharmaceutical companies continued to conduct studies to find the lowest doses of estrogen and progestogen effective as contraceptives and to market those products, women began to experience increased levels of intermenstrual bleeding. This observation led to the development of multiphasic oral contraceptives, a new approach to low-dose contraception.

Multiphasic oral contraceptives vary the dose of active ingredients or the ratio of progestogen to estrogen throughout the cycle, instead of maintaining a constant dose as in conventional fixed combination oral contraceptives. They utilize the lowest effective dose of active ingredients, but by varying the ratio, they attempt to better control intermenstrual bleeding. Some, but not all, of the low-dose multiphasic oral regimens studied significantly reduce intermenstrual bleeding and spotting [45]. The success of this approach was seen in the marketplace when the

first triphasic oral contraceptive was introduced in the United States (Ortho-Novum 7/7/7) in 1984. It rapidly became one of the most commonly prescribed oral contraceptives.

The next advance in the development of oral contraceptives was the discovery of new, pharmacologically more selective progestogens. The goal of synthesizing these more selective progestogens was to eliminate undesirable pharmacological activity but retain the required progestational/antiovulatory activity. Studies published in the 1970s and 1980s demonstrated that androgenicity, associated with the progestational component of some of the original progestogens, is associated with increased weight gain, an increased incidence of acne, and changes in lipid metabolism [46], [47], [48]. These latter changes may impact cardiovascular morbidity. Hence, oral contraceptives that do not disturb the various blood lipid fractions and do not lower HDL may be preferable to those that shift the lipid profile in an undesirable direction [49], [50]. Three companies, Johnson & Johnson's Ortho-McNeil division, Organon, and Schering AG, worked in this area, attempting to dissociate the unwanted androgenicity and desirable progestational activities of steroidal progestogens by using medicinal chemistry approaches. Norgestimate, desogestrel, and gestodene emerged from this research [51–56]. These new progestins had unique characteristics [48]. These more selective progestogens, in combination with ethinyl estradiol, compose the third-generation oral contraceptives (Table 2, see below). Norgestimate containing Ortho Tricyclen was ranked number one among U.S. oral contraceptives in 1998.

Synthetic progestogens used in today's oral contraceptives belong to one of three classes. Estranes are 19-nortestosterone derivatives; gonanes are 19-nortestosterone derivatives with a C-13 ethyl group; and pregnanesare 17-α-OH

Desogestrel

Gestodene

Norgestimate

Mestranol

Ethinyl estradiol

progesterone derivatives similar in structure to progesterone itself.

Only two synthetic estrogens have been used in oral contraceptives to date, ethinyl estradiol [*57-53-6*], 19-nor-17-pregna-1,3,5(10)-trien-20-yne-3,17-diol, $C_{20}H_{24}O_2$, M_r269.39, *mp* (hemihydrate) 141 – 146 °C, and mestranol [*72-33-3*], 3-methoxy-19-norpregna-1,3,5(10)-trien-20-yn-17-ol, $C_{21}H_{26}O_2$, M_r310.42, *mp* 150 – 151 °C. Ethinyl estradiol differs from naturally occurring estradiol-17β by having an ethinyl group attached to C-17, whereas mestranol differs from ethinyl estradiol by methylation of the hydroxyl group at C-3. Both of these steroids resemble the natural estrogens qualitatively in their actions on the reproductive tract, pituitary gland and hypothalamus. Mestranol probably exerts most of its pharmacological activity as ethinyl estradiol following demethylation at C-3.

It is now known that estrogen receptors in various target tissues differ and that a synthetic nonsteroidal estrogen analogue can have tissue-specific agonist activity, antagonist activity, or mixed pharmacological activity. Analogously to research on progestogens, this opens the possibility of finding a new generation of more selective estrogens for use in contraceptives. As a result, there is an increasing effort within the pharmaceutical industry and academia directed toward the search for tissue-selective estrogens which retain the desired pharmacological activity but minimize potential side effects. These efforts are enhanced by deeper knowledge of the pharmacological mechanisms that underlie the selective action of estrogens [57], the recently cloned new estrogen receptor ERβ [58], and tissue distribution of estrogen receptors α and β [59].

Since oral contraceptives were introduced in the 1960s, knowledge on the benefits and risks of oral contraceptives has increased. First, numerous studies have shown that oral contraception is the most effective and reversible means of preventing pregnancy [60]. Secondly, however, it is generally agreed that the use of oral contraceptives can slightly increase the risk of venous thromboembolism, ischemic heart disease, cerebrovascular disease and hypertension [61]. The thrombolic risk appears to be concentrated among older women who smoke and who use the older higher dose products. However, several recently published articles have reported that users of third-generation oral contraceptives containing gestodene and desogestrel may be at increased risk of venous thromboembolism (VTE) [39–44]. This increased risk was not observed for third-generation pills containing the progestin norgestimate [62], [63]. Regulatory reaction has varied from advising patients to restrict use of desogestrel or gestodene-containing products to making labeling changes [63]. Thirdly, many studies have shown that women appear to obtain other, beneficial effects from oral contraceptives in addition to protection against preg-

nancy. They include protection against pelvic inflammatory disease, ectopic pregnancy, endometrial cancer, cancer of the ovaries, benign breast disease, and benign ovarian cysts [61]. Relief from a wide range of menstrual disorders is also a known beneficial effect of oral contraceptives [61].

4.2. Progestogen-Only Oral Contraceptives

Sometimes termed the mini-pill, progestogen-only oral contraceptives are widely available throughout the world but are not used as extensively as combination oral contraceptives. These preparations contain progestational 19-norsteroids such as norethindrone, lynoestrenol, ethynodiol diacetate, or norgestrel; or 17-β-acetoxy progestogens such as chlormadinone acetate and megestrol acetate. In general, the contraceptive effectiveness of these products is lower than that of combination oral contraceptives, and intermenstrual or breakthrough bleeding and spotting occur more frequently. However, these products are valuable for women who are intolerant of estrogens, and there are fewer effects on breast feeding.

4.3. Long-Acting Contraceptives

The establishment of fertility regulation with hormonally active oral contraceptives led to the development of long-acting agents which could be delivered parenterally. Long-acting contraceptives avoid compliance issues, and are useful in countries with fewer health professionals. Their popularity is based on simplicity of administration and a relatively high degree of effectiveness. Efforts to develop long-acting contraceptives have included both chemical modifications of known progestogens for injectable administration and the use of new drug-delivery systems [64].

Two well-known injectable long-acting products are medroxyprogesterone acetate (Depo Provera) and norethindrone enanthate [*3836-23-5*] (NET EN). Both are progestational products. Depo Provera (Upjohn PharmaciaCompany) is a once-every-three-months injectable administered as a microcrystalline aqueous suspension of the steroid. NET EN (Schering AG) is a two-month injectable administered as a solution of steroid in castor oil. Depo Provera is approved for use as a contraceptive in more than ninety countries. NET EN is used in more than forty countries. Other products developed by chemically modifying known progestogens include 17α-hydroxyprogesterone caproate [*630-56-8*], $C_{27}H_{40}O_4$, and dihydroxyprogesterone acetophenide [*24356-94-3*], $C_{29}H_{36}O_4$. These monthly injectables are widely usedin Latin America.

Medroxyprogesterone acetate

Norethindrone enanthate

Like progestogen-only oral contraceptives, parenteral long-acting progestins act primarily as ovulation inhibitors. An important second mechanism of action is their effect on the cervical mucus and endometrium, achieved at circulating blood drug levels below those required for ovulation inhibition [65].

The major disadvantage of these long-acting injectable contraceptives is the side effect of irregular menses or amenorrhea. In an attempt to reduce this, long-acting injectable contraceptives containing both an estrogen and a progestogen are being studied, including dihydroxprogesterone acetophenide, norethisterone enanthate, medroxyprogesterone acetate and norethisterone in combination with estradiol esters such as their valerate, enanthate, or cypionate esters.

Drug-Delivery Systems. Research efforts have been directed at the use of new drug-delivery systems that release drug slowly over a prolonged period of time, such as silastic capsules, rods, or vaginal rings, and biodegradable implantable systems [66].

Nonbiodegradable Implants. The best known contraceptive implant is Norplant, developed by the Population Council in the United States. Norplant is composed of six matchlike silastic cylinders containing the progestogen levonorgestrel. After implantation under the skin, the product can provide effective contraception for a period of five years [67], [68]. Since silastic is not biodegradable, the implant can be removed at any time. The main reason patients request the removal of Norplant is unpredictable vaginal bleeding episodes followed by amenorrhea. The bleeding problem is an unavoidable sequel of progestogen-only contraception.

Biogradable Implants. Utilization of implantable biodegradable polymers obviates the need for implant removal. Technically, however, it is not as easy to develop such a product as it may appear. For example, biodegradation should not take place before drug release is finished; before that, sufficient structural integrity to permit surgical removal of the implant must be maintained. In addition, release rates for the drug must be sufficient to maintain blood levels of drug which will insure effective contraception.

An example of a biodegradable contraceptive implant is Capronor. This device has walls composed of σ-caprolactone; it releases levonorgestrel and is a single implant with projected life span of 12 – 18 months [66]. The timecourse for biodegradation and the disappearance of the implant are still being defined.

Fused pellets may be composed of the drug alone or the drug fused with cholesterol [53], [69], and are formed into small cylinders by melting the drug and then solidifying it under pressure. Clinical studies with norethindrone pellets have been in progress for a number of years. Polymeric implants and pellets require minor surgery for insertion and removal.

Microencapsulated Steroids. Microencapsulation of steroids to date has utilized polylactic acid (PLA), polyglycolic acid (PGA), and their copolymers (PLGA). The ratio of PLA to PGA determines the rate of steroid release. These thermoplastic biodegradable forms have been constructed as films, micropellets, microspheres, rods, and fibers [70].

Vaginal Rings. Vaginal epithelium is readily permeable to contraceptive steroids. Since the vascular drainage of the vagina bypasses the liver, this route of administration potentially permits utilization of drugs that have low oral activity due to degradation in the liver.

Contraceptive vaginal rings consist of silastic shells or core rings of various sizes and membrane thicknesses. They have been developed for delivery of progestins alone or progestins combined with estrogens. The biology behind progestin-alone rings is conceptually similar to that of implants, but the use of vaginal rings is under direct control of the patient since they can be inserted or removed at any time without a trained professional being present. After the ring is removed, a predictable withdrawal bleeding takes place. Vaginal rings have been under development for nearly 30 years by the WHO and the Population Council [71], [72]. Progress is being made. Materials have been selected which allow release of the active ingredient. Large clinical studies must still be done, but it is already known that higher doses and/or release rates are required for heavier women than for lighter women. Acceptability of this route of contraceptive drug administration must still be determined.

5. Intrauterine Devices (IUDs)

Intrauterine devices are medical products that prevent conception when placed in the uterus. In spite of their ancient origins, modern intrauterine devices (IUDs) have been widely used only in the last 30 years. The two generic subclasses of IUDs are nonmedicated (inert) devices and medicated IUDs, i.e., progestin-releasing or copper IUDs.

IUDs are used throughout the world, with an estimated 79 million users in 1989 [73]. They are a highly effective contraceptive method with protection rates for some devices reported to be 94 – 99 per 100 women for one year. Reviews are available on the efficacy and safety of this contraceptive method [74].

Complications associated with IUDs include uterine perforation and pelvic inflammatory dis-

ease [74]. Uterine bleeding and cramping are the most common causes for discontinuation of this method. The IUD's relationship to pelvic infection, fueled by the high rate of septic abortion and pelvic inflammatory disease (PID) among users of the Dalkon Shield IUD, led to a decline in the popularity of IUDs. In fact, all IUDs, except the progesterone-releasing Progestasert, were withdrawn from the U.S. market in the mid-1980s. With time, however, the realization that this effect appears to be limited to the Dalkon Shield led to the renewed interest in IUDs in the USA, and in 1988 the copper T-380A IUD (ParaGard) was introduced into the USA.

Inert IUDs act by creating an environment hostile to sperm or fertilized ova and by blocking implantation [75], [76]. The exact mechanism of action of IUDs is not totally clear, but convincing evidence is mounting to support the idea that IUDs act primarily as contraceptives and not as abortifacients [77]. Compared with noncontraceptors, IUD users have fewer recoverable sperm in the uteri and tubes after intercourse. In addition, there are fewer recoverable ova in the uteri and tubes at mid-cycle. Those ova found are rarely fertilized. In nonhuman primates, the rate of recovery of degenerating embryos is not significantly different from that seen among controls, in contrast to what might be expected if the IUD works by preventing embryo implantation. Transient elevations of human chorionic gonadotropin (hCG), which may indicate early pregnancy, were not more frequent among IUD users than among noncontraceptors [77].

After insertion of an IUD, polymorphonuclear leukocytes and macrophages accumulate in the uterine cavity. These cells appear to phagocytize sperm and liberate a blastotoxic toxin [78], [79]. Intrauterine devices also may create a hostile environment, perhaps because antibodies are produced that interfere with implantation of the fertilized ovum [79].

The range of IUDs available worldwide is considerable. Outside of China, the Lippes Loop, made of polyethylene, is the most widely used unmedicated IUD. The other main type of unmedicated IUD, used mostly in China, is a flexible stainless steel ring, i.e., the Chinese IUD.

Medicated IUDs consist of an inert base reservoir for a uterus-affecting or spermicidal agent such as progesterone or copper. Copper-bearing IUDs have spermicidal activity and interfere with implantation [80]. Two of these, the TCu-200 and the Multiload-250 (MLCu-250), are widely available except in China and the USA. The inclusion of progestogens in IUDs does not appear to improve their efficacy but may reduce the menstrual cramping and bleeding associated with IUD usage [81].

The second generation of copper IUDs have more copper wire, copper sleeves, and/or silver core in the copper wire, denoted by Ag in the IUD name. Significant second-generation IUDs include the TCu-380A, TCu-220C, Nova T, and Multiload-375 (MLCu-375); these are available worldwide, except for China.

Progestasert is a hormone-releasing IUD containing 38 mg progesterone, released at a rate of 65 μg/d for one year. It is available only in France and the USA. LNG-20, a long-lasting levonorgestrel-releasing IUD, is still under development in Europe.

6. Sterilization

Voluntary surgical sterilization of both men and women has increased in popularity. Sterilization has been running neck and neck with the oral contraceptive in terms of popularity, each chosen by about one in four couples.

Worldwide, an estimated 42 million couples rely on vasectomy; nearly 140 million rely on female sterilization [73]. Vasectomy is a principal family planning method in the USA, New Zealand, Australia, the UK, Canada, the Netherlands, China, India and South Korea. The method is hardly used in other countries [82].

In the 1970s, questions were raised about certain immunological complications as a consequence of male sterilization or vasectomy. Clinical epidemiological data do not appear to indicate that this actually occurs in clinical practice. No significant long-term side effects of male sterilization have been demonstrated.

Voluntary female sterilization is the world's most widely used family planning method. An estimated 138 million women of reproductive age used the method in 1990, 43 million more than in 1984. Millions more were expected to ask for the method during the 1990s [83].

Because of the increasing worldwide interest and demand for simple, effective and inexpensive female sterilization, a variety of procedures and methods have been developed. These approaches differ as to whether they are performed postpartum, postabortum, or in interval situations. The choice of method also largely depends upon the physician's prior training, knowledge, and experience. Reviews on sterilization are available [84].

7. Contragestational Drugs

Pharmacological substances that either inhibit implantation or interrupt pregnancy after implantation were investigated during the 1980s and 1990s. A number of different terms have been used to describe these compounds [47–63], including anti-implantive agents, post-coital contraceptives, morning-after pills, emergency contraceptives, once-a-week pills, interceptives, abortifacients, and contragestational agents. This medical approach to fertility regulation presents several principal advantages, including potentially fewer long-term side effects as a result of short-term periodic administration and greater convenience.

However, in the decision to develop and market contragestational drugs, social, political, legal, ethical, and religious factors have been of critical importance.

Post-Coital Contraception. Post-coital contraception historically has been viewed as an emergency measure where regular contraception was not used or where the primary contraceptive methods may have failed. A number of approaches have been utilized in post-coital regimens. Early regimens utilized high doses of the estrogens [84] diethylstilbestrol, ethinyl estradiol, and the conjugated equine estrogens (Premarin). Characteristically, the drugs are taken for a period of three days. When given later than 72 h after coitus, the effectiveness is reduced; the drugs are ineffective if implantation has been established. Although the estrogens are highly effective, users suffer from a high incidence of nausea and vomiting; cycle regularity also is disturbed. A similar approach has been reported for levonorgestrel-containing contraceptives [86], [87].

The U.S. FDA recently approved specific regimen of combination oral contraceptives containing levonorgestrel and ethinyl estradiol as safe and effective for post-coital pregnancy prevention in women who have had unprotected sexual intercourse. The regimen consists of two oral contraceptive tablets taken within 72 h of intercourse and two pills taken 12 h later. When used in this manner, the treatment is about 75 % effective in preventing pregnancy. The treatment does not work if a woman is already pregnant.

Danazol is also highly effective in post-coital regimens and has a very low incidence of side effects. Danazol is marketed in many countries for the treatment of endometriosis and its availability is unrestricted. There is apparently no significant difference in effectiveness when doses of 800 to 1200 mg have been utilized for three days [86], [88]. When utilized in the post-coital mode, the precise mechanism of action of Danazol is not well-understood.

A nonsteroidal weekly pill, centchroman [*31477-60-8*] [16], was developed by the Central Drug Research Institute, Lucknow, India, and is being marketed as Choice-7 and Sahali (Hindustan Latex). Centchroman, (3,4-*trans*-2,2-dimethyl-3-phenyl-4-[*p*-β-pyrrolidino-ethoxy)-phenyl]-7-methoxychromane) inhibits implantation of the fertilized egg, thus avoiding pregnancy [89]. It exerts its antifertility effect by weak estrogenic and potent anti-estrogenic activity [90]. Although the synthesis and pharmacological actions of centchroman have been well documented [91], overall efficacy and side effects are not known or described except in a brief description of the product. A Pearl index (i.e., average of pregnancies out of 100 women who use the specific contraceptive for one year) of 3.05 was calculated for the administration of weekly doses of centchroman (30 mg) to

Centchroman

approximately 1600 women for a total of 20 000 months [89].

Abortifacients. It is estimated that between 30 and 40 million legal abortions and an equal number of illegal abortions are carried out each year worldwide. Most abortions are induced because the pregnancy is unintended and unwanted. In the USA, about 60 % of all pregnancies are unwanted or mistimed, half of which are aborted [92].

In mammals, removal of the corpus luteum during early pregnancy results in termination of pregnancy. Pharmacologically, this can be accomplished by various methods, including inhibition of gonadotropin support of the corpus luteum, inhibition of progesterone biosynthesis in the ovary, inhibition of progesterone binding to the uterine progestin receptor, and increase in the metabolism of progesterone. Many compounds that affect these processes have been reported [93]; some of these have been introduced for clinical study.

Chemically induced abortion originally involved the administration of the natural prostaglandin $F_{2\alpha}$ [*551-11-1*] (Dinoprost, $C_{20}H_{34}O_5$) and synthetic analogues such as sulprostone [*60325-46-4*], $C_{23}H_{31}NO_7S$, and prostaglandin ONO 802, [*64318-79-2*] (Gemeprost, $C_{23}H_{38}O_5$) have also been reported [94]. After administration of relatively small amounts of these prostaglandins, the muscle tone of the uterus increases, followed by contractions, cervical dilation and expulsion of the uterine contents. The usefulness of prostaglandins for termination of pregnancy is limited because of a high frequency of gastrointestinal side effects.

In 1988, the French government approved the marketing of an abortion pill. RU486 [*84371-65-3*] (Mifepristone), an antiprogestin developedby the French pharmaceutical company Roussel-UCLAF. It is the first clinicallyuseful progesterone antagonist. A review of the chemistry, pharmacology, and clinical applications of this compound [95] is available, as is a review on the use of RU486 alone or in combination with a prostaglandin analogue for termination of early pregnancy [96]. Other studies suggest the use of antiprogestins for contraception and for treatment of gynecological disorders related to hormone production [97]. The discovery of RU486 was followed by laboratory and clinical studies with other antiprogestins, including ZK98 299 and ZK98 734 [98]. Many issues, not only scientific, but also political and religious,

Prostaglandin $F_{2\alpha}$

Sulprostone

Prostaglandin ONO 802

RU468 (Mifepristone)

ZK98 734 (Lifopristone)

ZK98 299 (Onapristone)

surround the clinical application of progesterone antagonists, and it is difficult to project worldwide availability of RU486 and related products.

8. New Approaches

There are no methods of fertility regulation available today that are totally safe and effective or that appeal to all groups and societies in the world. Therefore, there continues to be great interest in developing new and improved contraceptives. In addition to utilizing new technology, new contraceptives should be superior to existing products. For example, oral contraceptives, used by millions of women over the last 30 years, are not only safe and effective but even protect women against some cancers. Because oral contraceptives are so effective, they have become a very high standard that other products must meet.

Contraceptive Vaccines. Major research efforts involve immunological approaches to fertility control; for reviews, see [99, 100, 102, 102]. The development of contraceptive vaccines is directed towards the immunoneutralization of the reproductive process or interfering with fertilization by inducing antibodies against oocytes and spermatozoa. Attempts have been made to develop vaccines against luteinizing hormone releasing hormone (LHRH) (also known as gonodotropin releasing hormone, or GnRH), LH, follicle stimulating hormone (FSH), human chorionic gonadotropin (hCG), placenta antigen, the zona pellucida of the ovum, and different sperm antigens.

Research on an hCG vaccine has been conducted over the past 20 years. The WHO has conducted a Phase I clinical study in Australia, using a vaccine based on a synthetic C-terminal peptide (109-141) of β-hCG conjugated to Diptheria Toxoid (CTP-DT). This study demonstrated that potentially effective contraceptive levels of antibodies were produced in vaccinated women without any adverse side effects. Phase II clinical studies are under consideration to determine if the immune response to the prototype anti-hCH vaccine is capable of preventing pregnancy in fertile women volunteers [103]. While research on the C-terminal peptide from the β-subunit of hCG has been carried out under the auspices of WHO, research supported by the Population Council and the NIH has involved two alternative vaccine candidates [101], [104].

By using advanced technologies, unique sperm antigens have been identified and partially characterized. Sperm antigens shown to have high immunocontraceptive potential are human sperm membrane antigen (SP-10) and guinea pig sperm membrane protein (PH-20). SP-10 is a sperm membrane-specific antigen of 24 – 34 kD, isolated by using a monoclonal antibody (MHS-10) that cross-reacts with the entire acrosomal region. It is associated with the outer aspect of the inner acrosomal membrane and the inner aspect of the outer acrosomal membrane of mature human sperm [104]. It has been produced recombinantly in an *E. coli* expression system. The recombinant SP-10 fusion protein is under study in the baboon.

PH-20, a guinea pig sperm protein of 64 kD, is present on both the plasma membrane and inner acrosomal membrane of sperm. It is essential for adhesion of sperm to the zona pellucida, the initial step in the fertilization process. Active immunization with PH-20 causes infertility in both male and female guinea pigs for a period ranging from six to fifteen months [105].

Another interesting sperm specific antigen is lactic dehydrogenase-x (LDH-x or $LDHC_4$), an isoenzyme of LDH confined to male germ cells. LDH-x is one of the best characterized antigens and its amino acid sequence is known. A synthetic peptide based on a portion of the molecule has been shown to reduce fertility in laboratory animals. The nucleotide sequence coding for human LDH-x has been defined and engineered into an expression vector system [100].

The zono pellucide (ZP) is the complex extracellular glycoprotein matrix that surrounds the oocyte. It plays an important role in sperm penetration and fertilization. It is a composite of several antigenic glycoproteins designated ZPI, ZPII, ZPIII, and, in some species, ZPIV. Immunologically, it does not cross-react with any other body tissues, but interspecies cross-reactivity has been observed among several species, including primates. Numerous studies indicate the immunocontraceptive potential of zona pellucida [100]. Several other antigens with good immunocontraceptive potential have been identified and investigated in laboratory animals.

In most immunocontraceptive studies to date, however, the rate and duration of immunocontraceptive effects have been less than acceptable. Two problems which are faced in immunological approaches to antifertility research is the need for a safe, effective adjuvant and suitable animal models for evaluating the efficacy and safety of the adjuvants [99]. Newer and more effective adjuvants are required for contraceptive vaccines and vaccines in general.

Luteinizing Hormone Releasing Hormone. The isolation and synthesis of luteinizing hormone releasing hormone (LHRH) was an important advance in reproductive research [122]. LHRH is a peptide hormone produced and secreted by the hypothalamus that stimulates the secretion of FSH and LH. A decapeptide with an amino acid sequence of pyroGlu-His-Trp-Ser-Tyr-Gly-Leu-Arg-Pro-Gly-NH_2, it is chemically and functionally similar in both males and females of all mammalian species studied thus far. More than 1000 analogues of LHRH have been synthesized by deletion or substitution of amino acids to introduce agonist or antagonist properties. A large number of reviews have appeared discussing their therapeutic importance [106–108].

These agonists and antagonists may provide useful therapy for several clinical conditions such as prostatic carcinoma, precocious puberty, and endometriosis. Scientists are also studying LHRH analogues for contraception [109]. Treatment with LHRH analogues blocks ovulation in women and spermatogenesis in men. However, treatment also results in a loss of estrogen and testosterone and causes other related side effects. Scientists are attempting to assess the use of these agents in combination with replacement estrogen, progesterone, and testosterone to determine if the side effects can be avoided. Several small nonhuman primate and clinical studies have suggested possible utility in this area, but large-scale clinical efficacy studies have not been conducted.

Progesterone Antagonists as Contraceptives. Progesterone is required to maintain pregnancy in women, and infertility results from failure of the corpus luteum to produce adequate amounts of progesterone. Inhibitors of progesterone synthesis, such as epostane [110], and inhibitors of progesterone-receptor binding, such as RU486, have been investigated for termination of pregnancy. Studies in the nonhuman primate and nonpregnant women indicate that progesterone antagonists may also have antifertility potential other than as an abortifacient [88], [111].

Inhibin and Activin. Inhibin, a water-soluble, gonadal factor known for over 50 years to inhibit pituitary function, has been isolated and identified [112–115]. Inhibin is a glycoprotein hormone that preferentially inhibits the secretion of FSH. It consists of an α-chain subunit, M_r 14000, linked by disulfide bonds to a β-chain subunit, M_r 18000. There are two forms of the β-chain subunit, β-A and β-B. The smaller subunit combines with either the β-A or β-B subunit to form inhibin-A or inhibin-B, respectively.

During the isolation of inhibin from follicular fluid, it was found that some chromatographic fractions stimulated FSH release from cultured anterior pituitary cells, suggesting the existence of FSH releasing proteins (FRPs). Two FRPs, given the generic term activins, were subsequently isolated [116], [117]. One is composed of two disulfide-linked β-A subunits (activin A); the other consists of similarly linked β-A and β-B subunits (activin AB).

Studies confirm that inhibin plays a role in regulating FSH secretion. However, the importance of this role in humans has not yet been determined. If inhibin-regulated FSH secretion is pivotal in follicular recruitment and growth, then it may be possible to block ovulation by means of inhibin antagonists.

Activin has the potential to serve the same therapeutic uses as GnRh analogues. This is because of its ability to regulate steroidogenesis directly at the gonadal level. Although the spectrum of functions of inhibin and activin are not completely understood at present, this peptide family has already demonstrated, by the nature of its differential subunit association, a powerful mechanism for the generation of dimers with opposing biologic actions. These characteristics of the inhibin peptide family warrant further study and evaluation as alternative approaches to fertility control.

Male Fertility Control. There is interest in male fertility control, both from a scientific as

well as from a sociological viewpoint. Many compounds have been identified as having male antifertility activity in various species, e.g., gossypol [*303-45-7*], ORF 5513, 5-thio-D-glucose [*20408-97-3*], and 6-chlorodeoxy-glucose [118]. A program based on the use of androgens has also been conducted [119].

Organic molecules thus far identified, such as those listed above, appear either to have irreversible antifertility effects, to be inherently toxic, or to affect libido. With respect to androgens, it has been demonstrated that sperm count can be depressed but not eliminated in men injected with large doses of androgens. However, questions about the potential utility of androgens as male antifertility agents are still debated, not least of which is whether lowering, but not eliminating sperm, will provide effective male contraception.

The ideal male contraceptive would produce azoospermia without compromising libido and sexual potency. While not totally fulfilling the criteria for a perfect male contraceptive, GnRH antagonists hold a greater potential than GnRH agonists. Unlike the agonists, GnRH antagonists inhibit gonodotropin secretion, decrease androgen levels, and induce azoospermia in male primates [120], [121]. Similar effects on hormone secretion have been reported in men [115].

In monkeys, testosterone replacement delays, but does not prevent, GnRH antagonist-induced azoospermia [122]. In men, the combination of testosterone and a GnRH antagonist results in a more complete gonadotropin and gonadal suppression than either agent alone [123]. These results suggest that GnRH antagonists, given in conjunction with androgens to maintain libido and sexual potency, have potential as male contraceptives. More recently the WHO and other research groups are actively pursuing the use of androgen plus progestogens as male contraceptives. Reviews of male contraceptive research are available [124], [125].

1. Introduction

Copper [*7440-50-8*], the red metal, apart from gold the only metallic element with a color different from a gray tone, has been known since the early days of the human race. It has always been one of the significant materials, and today it is the most frequently used heavy nonferrous metal. The utility of pure copper is based on its physical and chemical properties, above all, its electrical and thermal conductivity (exceeded only by silver), its outstanding ductility and thus excellent workability, and its corrosion resistance (a chemical behavior making it a half-noble metal).

Its common alloys, particularly brass and bronze, are of great practical importance (→ Copper Alloys). Copper compounds and ores are distinguished by bright coloration, especially reds, greens, and blues (→ Copper Compounds). Copper in soil is an essential trace element for most creatures, including humans.

Etymology. According to mythology, the goddess Venus (or Aphrodite) was born on the Mediterranean island of Cyprus, formerly *Kypros* (Greek), where copper was exploited millennia before Christ. Therefore, in early times the Romans named it cyprium, later called cuprum. This name is the origin of *copper* and of the corresponding words in most Romance and Germanic languages, e.g., cobre (Spanish and Portuguese), cuivre (French), Kupfer (German), koper (Dutch), and koppar (Swedish).

History [21–24]. The first metals found by Neolithic man were gold and copper, later silver and meteoric iron. The earliest findings of copper are presumed to be nearly nine millennia old and came from the region near Konya in southern Anatolia (Turkey). Until recently the six-millennia-old copper implements from Iran (Tepe Sialk) were presumed to be the oldest. In the Old World, copper has been worked and used since approximately

7000 B.C.	Anatolia
4000 B.C.	Egypt, Mesopotamia, Palestine, Iran, and Turkestan
3000 B.C.	Aegean, India
2600 B.C.	Cyprus
2500 B.C.	Iberia, Transcaucasia, and China
2200 B.C.	Central Europe
2000 B.C.	British Isles
1500 B.C.	Scandinavia

Empirical experience over millennia has led to an astonishing knowledge of copper metallurgical operations:

1) Native copper was hardened by hammering (cold working) and softened by moderate heating (annealing).
2) Heating to higher temperatures (charcoal and bellows) produced molten copper and made possible the founding into forms of stone, clay, and later metal.
3) Similar treatment of the conspicuously colored oxidized copper ores formed copper metal.
4) The same treatment of sulfide copper ores (chalcopyrite), however, did not result in copper metal, but in copper matte (a sulfidic intermediate). Not before 2000 B.C. did people succeed in converting the matte into copper by repeated roasting and smelting.
5) In early times, bronze (copper – tin alloy) was won from complex ores, the Bronze Age beginning ca. 2800 B.C. At first, copper ores were smelted with tin ores; later, bronze was produced from metallic copper and tin. Brass (copper – zinc alloy) was known ca. 1000 B.C. and became widely used in the era of the Roman Empire.

In Roman times, most copper ore was mined in Spain (Rio Tinto) and Cyprus. With the fall of the Roman Empire, mining in Europe came to a virtual halt. In Germany (Saxony), mining activities were not resumed until 920 A.D. During the Middle Ages, mining and winning of metals expanded from Germany over the rest of Europe. In the middle of the 16th century, the current knowledge of metals was compiled in a detailed publication [23] by GEORGIUS AGRICOLA, *De Re Metallica* (1556).

Independent of the Old World, the Indians of North America had formed utensils by working native copper long before the time of Christ, although the skills of smelting and casting were unknown to them. On the other hand, the skill of copper casting was known in Peru ca. 500 A.D., and in the 15th century the Incas knew how to win the metal from sulfide ores.

Around 1500, Germany was the world leader in copper production, and the FUGGER family dominated world copper trade. By 1800, England had gained first place, processing ores from her own sources and foreign pits into metal. Near 1850, Chile became the most important producer of copper ores, and toward the end of the last century, the United States had taken the world lead in mining copper ores and in production of refined copper.

Technical development in the copper industry has made enormous progress in the last 120 years. The blast furnace, based on the oldest principle of copper production, was continually developed into more efficient units. Nevertheless, after World War I, it was increasingly replaced by the reverberatory furnace, first constructed in the United States. Since the end of World War II, this furnace has been superseded slowly by the flash smelting furnace invented in Finland. Recently, several even more modern methods, especially from Canada and Japan, have begun to compete with the older processes.

An important development in producing crude metal was the application of the Bessemer converter concept to copper metallurgy by

MANHÈS and DAVID (France, 1880): this principle is still the most widely used method for copper converting in the world.

Over time the requirements for copper purity have become increasingly stringent. The invention and development of electrolysis by J. B. ELKINGTON (England, 1865) and E. WOHLWILL (Germany, 1876) made refining of high-purity copper possible.

In addition, the quantity of copper produced has increased immensely (Table 1). Since 1800, ca. 375×10^6 t of primary copper has been mined in the world, but of this only ca. 10×10^6 t was mined between 1800 and 1900.

Table 1. World mine production of copper (approximate, from several sources)

Year	Production, 10^3 t	Year	Production, 10^3 t
1700	9	1970	6400
1800	17	1975	7300
1850	57	1980	7900
1900	450	1985	8300
1950	2500	1990	9225
1955	3100	1995	10 050
1960	4200	1997	11 525
1965	5000		

2. Physical Properties

Most properties of copper metal depend on the degree of purity and on the source of the metal. Variations in properties are caused by

1) Grade of copper, i.e., the oxygen content: tough-pitch copper, deoxidized copper, oxygen-free copper
2) Content of native impurities (e.g., arsenic, bismuth) or remnants of additives (e.g., phosphorus), which form solid solutions or separate phases at the grain boundaries
3) Thermal and mechanical pretreatment of the metal, which lead to states such as cast copper, hot-rolled copper, cold-worked (hard) copper, annealed (soft) copper, and sintered copper

These property differences are caused by the defects in the crystal lattice. Two groups of properties are to be distinguished:

1) Low dependence on crystal lattice defects, e.g., caloric and thermodynamic properties, magnetic behavior, and nuclear characteristics
2) High dependence on defects, e.g., electrical and thermal conductivity, plastic behavior, kinetic phenomena, and resistance to corrosion

The variations in properties are caused either by physical lattice imperfections (dislocations, lattice voids, and interstitial atoms) or by chemical imperfections (substitutional solid solutions).

Atomic and Nuclear Properties. The atomic number of copper is 29, and the atomic mass A_r is 63.546 ± 0.003 (IUPAC, 1983). Copper consists of two natural isotopes, ^{63}Cu (68.94 %) and ^{65}Cu (31.06 %). There are also nine synthetic radioactive isotopes with atomic masses between 58 and 68, of which ^{67}Cu has the longest half-life, ca. 58.5 h.

Crystal Structure. At moderate pressures, copper crystallizes from low temperatures up to its melting point in a cubic closest-packed (ccp) lattice, type A 1 (also F[1] or Cu) with the coordination number 12. X-ray structure analysis yields the following dimensions (at 20 °C):

Lattice constant	0.36152 nm
Minimum interatomic distance	0.2551 nm
Atomic radius	0.1276 nm
Atomic volume	7.114 cm^3/mol

There is also a high-pressure modification, which forms at ca. 400 MPa and 100 °C.

Density. The theoretical density at 20 °C, computed from lattice constant and atomic mass is 8.93 g/cm^3. The international standard was fixed at 8.89 g/cm^3 in 1913 by the IEC (International Electrotechnical Commission). The maximum value for 99.999 % copper reaches nearly 8.96 g/cm^3.

The density of commercial copper depends on its composition, especially the oxygen content, its mechanical and thermal pretreatment, and the temperature. At 20 °C, a wide range of values are found:

Cold-worked and annealed copper	8.89 – 8.93 g/cm^3
Cast tough-pitch electrolytic copper	8.30 – 8.70 g/cm^3
Cast oxygen-free electrolytic copper	8.85 – 8.93 g/cm^3

The values for cold-worked copper are higher than those of castings because the castings have pores and gas cavities.

The density of copper is nearly a linear function of temperature, with a discontinuity at the melting point:

Temperature, °C	Density, g/cm^3
solid copper	
20	8.93
600	8.68
900	8.47
1 083	8.32
liquid copper	
1 083	7.99
1 200	7.81

The solidification shrinkage is 4 %; the specific volume at 20 °C is 0.112 cm^3/g.

Mechanical Properties. Important mechanical values are given in Table 2. High-purity copper is an extremely ductile metal. Cold working increases the hardness and tensile strength (hard or hard-worked copper); subsequent annealing eliminates the hardening and strengthening so that the original soft state can be reproduced (soft copper). The working processes are based on this behavior (Section 7.1). Impurities that form solid solutions of the substitutional type likewise increase hardness and tensile strength.

Table 2. Mechanical properties of copper at room temperature

Property	Unit	Anealed (soft) copper	Cold-worked (hard) copper
Elastic modulus	GPa	100 – 120	120 – 130
Shearing modulus	GPa	40 – 45	45 – 50
Poisson's ratio		0.35	
Tensile strength	MPa	200 – 250	300 – 360
Yield strength	MPa	40 – 120	250 – 320
Elongation	%	30 – 40	3 – 5
Brinell hardness	(HB)	40 – 50	80 – 110
Vickers hardness	(HV)	45 – 55	90 – 120
Scratch hardness		≈3	

Pure copper has outstanding hot workability without hot brittleness, but the high-temperature strength is low. Detrimental impurities, those that decrease the strength at high temperatures, are principally lead, bismuth, antimony, selenium, tellurium, and sulfur. The concentration of oxides of such elements at the grain boundaries during heating causes the embrittlement. However, such an effect can be desirable when free cutting is required. At subzero temperatures, copper is a high-strength material without cold brittleness.

The changes in typical mechanical properties such as tensile strength, elongation, and hardness by heat treatment result from recrystallization [25]. The dependence of recrystallization temperature and grain size on the duration of heating, the amount of previous cold deformation, and the degree of purity of copper can be determined from diagrams. The recrystallization temperature is ca. 140 °C for high-purity copper and is 200 – 300 °C for common types of copper. A low recrystallization temperature is usually advantageous, but higher values are required to maintain strength and hardness if the metal is heated during use.

Thermal Properties. Important thermal values are compiled in Table 3. The thermal conductivity of copper is the highest of all metals except silver.

Table 3. Thermal properties of copper

Property	Unit	Value
Melting point	K	1356 (1083 °C)
Boiling point	K	2868 (2595 °C)
Heat of fusion	J/g	210
Heat of vaporization	J/g	4810
Vapor pressure (at *mp*)	Pa	0.073
Specific heat capacity		
at 293 K (20 °C)		
and 100 kPa (1 bar)	J g^{-1} K^{-1}	0.385
at 1230 K (957 °C)		
and 100 kPa		0.494
Average specific heat		
273 – 573 K (0 – 300 °C)		
at 100 kPa (1 bar)	J g^{-1} K^{-1}	0.411
273 – 1273 K (0 – 1000 °C)		
at 100 kPa		0.437
Coefficient of linear thermal expansion		
273 – 373 K (0 – 100 °C)	K^{-1}	16.9×10^{-6}
273 – 673 K (0 – 400 °C)		17.9×10^{-6}
between 273 and 1173 K (0 – 900 °C)		19.8×10^{-6}
Thermal conductivity		
at 293 K (20 °C)	W m^{-1} K^{-1}	394

Electrical Properties. In practice, the most important property of copper is its high electrical conductivity; among all metals only silver is a better conductor. Both electrical conductivity and thermal conductivity are connected with the Wiedemann – Franz relation and show strong dependence on temperature (Table 4). The old American standard, 100 %

IACS (International Annealed Copper Standard), corresponds to 58.0 MS/m at 20 °C, and it is still widely used in the United States. The corresponding electrical resistivity (ϱ) is $1.7241 \times 10^{-8}\,\Omega \cdot$ cm, and the less usual resistivity based on weight (density of 8.89 g/cm^3, IEC) is $0.1533\,\Omega\,\mathrm{g\,m^{-1}}$. The corresponding temperature coefficients are $0.0068 \times 10^{-8}\,\Omega\,\mathrm{m\,K^{-1}}$ ($\mathrm{d}\varrho/\mathrm{d}T$) and $0.00393\,\mathrm{K^{-1}}$ ($\varrho^{-1}\mathrm{d}\varrho/\mathrm{d}T$). The theoretical conductivity at 20 °C is nearly 60.0 MS/m or 103.4 % IACS, and today commercial oxygen-free copper (e.g., Cu-OF) has a conductivity of 101 % IACS.

Table 4. Temperature dependence of thermal and electrical conductivity of copper

Temperature		Thermal conductivity, $\mathrm{W\,m^{-1}\,K}$	Electrical conductivity, MS/m
K	°C		
17	−256	5 000	
73	−200	574	460
113	−160	450	
173	−100	435	110
273	0	398	60
293	20	394	58
373	100	385	44
473	200	381	34
573	300	377	27
973	700	338	15

The factors that increase the strength decrease electrical conductivity: cold working and elements that form solid solutions. Elements that form oxidic compounds that separate at grain boundaries affect electrical properties only slightly. Copper may lose up to ca. 3 % of its conductivity by cold working; however, subsequent annealing restores the original value. There is a simple rule: the harder the copper, the lower is its conductivity.

Other Properties. High-purity copper is diamagnetic with a mass susceptibility of -0.085×10^{-6} cm^3/g at room temperature. The dependence on temperature is small. However, a very low content of iron can strongly affect the magnetic properties of copper.

The lower the frequency of light, the higher the reflectivity of copper. The color of a clean, solid surface of high-purity copper is typically salmon red.

The surface tension of molten copper is 11.25×10^{-3} N/cm at 1150 °C, and the dynamic viscosity is 3.5×10^{-3} Pa · s at 1100 °C.

Detailed physical-property information and data are to be found in the literature, particularly as tabular compilations [25–30].

3. Chemical Properties

In the Periodic Table copper is placed in the first transition series (period 4). It belongs to Group 11 and, together with silver and gold, forms the coinage metals. Its electron configuration is [Ar] $3d^{10}\,4s^1$. Copper compounds are known in oxidation states ranging from +1 to +4, although the +2 (cupric) and the +1 (cuprous) are by far the most common. In aqueous solutions or below 800 °C, the +2 oxidation state is the most stable.

Copper(I) compounds such as CuCl and CuI are diamagnetic colorless materials, except for those whose color results from charge-transfer bands, for example, Cu_2O. Cu^+ ions, [Ar] $3d^{10}$, are coordinated in a linear (two ligands) or tetrahedral fashion (four ligands).

Copper(II) compounds such as $CuSO_4 \cdot 5\,H_2O$ are paramagnetic blue or green substances, the color of which results from strong absorption bands in the region between 600 and 900 nm caused by $d-d$ electron transfer processes. The Cu^{2+} ion is a d^9 system and generally sixfold coordinated in a distorted octahedral manner.

Copper(III) compounds are mostly diamagnetic. Cuprates like $NaCuO_2$ can be obtained by heating the oxides in pure oxygen. In chemistry only a few Cu^{3+} complexes are known, but it appears that Cu^{3+} plays an important role in biochemistry, especially with deprotonated peptides.

Copper(IV) compounds are not well known except for $Cs_2[CuF_6]$.

Behavior in Air. Copper in dry air at room temperature slowly develops a thin protective film of copper(I) oxide [*1317-39-1*]. On heating to a high temperature in the presence of oxygen, copper forms first copper(I) oxide, then copper(II) oxide [*1317-38-0*], both of which cover the metal as a loose scale.

In the atmosphere, the surface of copper oxidizes in the course of years to a mixture of green basic salts, the patina, which consists chiefly of the basic sulfate, with some basic carbonate. (In a marine atmosphere, there is also some basic chloride.) Such covering layers protect the metal.

Behavior versus Diverse Substances. While many substances scarcely react with copper under dry conditions, the rate of attack increases considerably in the presence of moisture. Copper has a high affinity for free halogens, molten sulfur or hydrogen sulfide.

Standard electron potentials of copper are as follows [31], [32]:

Potentials in standard (acid) solution:

$$Cu^{+} + e^{-} \longrightarrow Cu \quad E_0 = 0.521\ V$$

$$Cu^{2+} + 2e^{-} \longrightarrow Cu \quad E_0 = 0.153\ V$$

Potentials with complexing ligands:

$$[Cu(NH_3)_4]^{2+} + 2e^{-} \longrightarrow Cu + 4NH_3 \quad E_0 = -0.11\ V$$

$$[Cu(CN)_2]^{-} + e^{-} \longrightarrow Cu + 2CN^{-} \quad E_0 = -0.43\ V$$

As the standard electron potentials show, copper metal is stable to nonoxidizing acids like dilute sulfuric or hydrochloric acid, similar to the precious metals. Dissolution of copper is possible in oxidizing acids such as nitric acid or hot concentrated sulfuric acid. Also other redox systems such as iron(III) or copper(II) chloride solutions are suitable reagents for leaching copper in practice.

Copper dissolves not only in oxidizing acids but also, for example, in ammonia or cyanide solutions in the presence of oxygen because stable complexes are formed. Also acetic acid together with oxygen or hydrogen peroxide attacks copper forming a green pigment called verdigris.

Free Cu^{+} ions are not stable in aqueous solution although Cu^{+} ($3d^{10}$) has a filled d shell. Spontaneous disproportion into Cu^{2+} and Cu takes place.

$$2Cu^{+} \longrightarrow Cu^{2+} + Cu \quad E_0 = 0.37\ V$$

$$K = [Cu^{2+}]/[Cu^{+}] = 10^6$$

The distorted octahedral coordination of six water molecules around the Cu^{2+} ion (d^9) gives an additional stabilization energy (ligand-field effect). In aqueous solutions, Cu^{+} is only existent in form of very stable complexes like $[Cu(CN)_2]^{-}$ or in the presence of an excess of copper metal. Also, insoluble Cu^{+} compounds such as cuprous oxide do not disproportionate in water.

By virtue of its large ionic radius and low electrical charge, the Cu^{+} ion is a soft acid. Therefore, the chemistry of copper in the oxidation state + 1 is predominated by reactions with soft bases like iodine (CuI), sulfur (CuSCN), or unsaturated nitrogen ligands. In contrast, the chemistry of Cu^{2+}, which is smaller and more highly charged, is dominated by hard ligands like oxygen ($[Cu(H_2O)_6]^{2+}$) or nitrogen ($[Cu(NH_3)_4]^{2+}$).

Copper is very stable in fresh water and also in sea water or alkali metal hydroxide solutions. Wastewater containing organic sulfur compounds can be corrosive to copper.

Figure 1. Pourbaix diagram for copper in highly dilute aqueous solution at normal temperature [35]

Corrosion [33], [34]. M. J. N. Pourbaix has developed potential – pH equilibrium diagrams for metals in dilute aqueous solutions [35]. Such graphs give a rough indication of the feasibility of electrochemical reactions. Figure 1 shows the behavior of copper at room temperature and atmospheric pressure. The $Cu - H_2O$ system contains three fields of different character:

1) Corrosion, in which the metal is attacked
2) Immunity, in which reaction is thermodynamically impossible
3) Passivity, in which there is no reaction because of kinetic phenomena

Gases and Copper [36], [37]. An exact knowledge of the behavior of solid and liquid copper toward gases is important for production and use of the metal. With the exception of hydrogen, [*1333-74-0*], the solubility of gases in molten copper follows Henry's law: the solubility is proportional to the partial pressure.

Oxygen [*7782-44-7*] dissolves in molten copper as copper(I) oxide up to a concentration of 12.6 wt % Cu_2O (corresponding to 1.4 wt % O) (also see Fig. 32). Copper(I) oxide in solid copper forms a separate solid phase.

Sulfur dioxide [*7446-09-5*] dissolves in molten copper and reacts:

$$6\,Cu + SO_2 \rightleftharpoons Cu_2S + 2\,Cu_2O$$

Hydrogen is considerably soluble in liquid copper, and after solidification some remains dissolved in the solid metal, although copper does not form a hydride. The solubility follows Sievert's law, being proportional to the square root of the partial pressure because the H_2 molecules dissociate into H atoms on dissolution. Hydrogen has high diffusibility because of its extremely small atomic volume.

Hydrogen dissolved in oxygen-bearing copper reacts with copper(I) oxide at high temperatures to form steam:

$$Cu_2O + 2\,H \rightleftarrows 2\,Cu + H_2O(g)$$

Steam is not soluble in copper; therefore, it either escapes or forms micropores.

Nitrogen, carbon monoxide, and carbon dioxide are practically insoluble in liquid or solid copper. Hydrocarbons generally do not react with copper. An exception is acetylene, which reacts at room temperature to form the highly explosive copper acetylides Cu_2C_2 and CuC_2; therefore, acetylene gas cylinders must not be equipped with copper fittings.

4. Occurrence

In the upper part of the earth's crust (16 km deep), the average copper content is ca. 50 ppm. It is thus about half as abundant as chromium, about twice as abundant as cobalt, and 26th in order of abundance of the elements in the accessible sphere of the earth. Table 5 shows average copper contents in natural materials.

Table 5. Typical copper contents of natural materials

Mineral	Content, ppm
Basalt	85
Diorite	30
Granite	10
Sandstone	1
Copper ores (poor)	5 000
Copper ores (rich)	50 000
Native copper	950 000
Seawater	0.003
Deep-sea clays	200
Manganese nodules	10 000
Marine ore sludges	10 000
Earth's crust (average)	50
Meteorites (average)	180

4.1. Copper Minerals

More than 200 minerals contain copper in definable amounts, but only about 20 are of importance as copper ores (Table 6) or as semiprecious stones (turquoise and malachite). Copper is a typical chalcophilic element; therefore, its principal minerals are sulfides, mostly chalcopyrite, bornite, and chalcocite, often accompanied by pyrite, galena, or sphalerite.

Secondary minerals are formed in sulfide ore bodies near the earth's surface in two stages. In the oxidation zone, oxygen-containing water forms copper oxides, basic salts (basic carbonates and basic sulfates), and silicates. In the deeper cementation zone, copper-bearing solutions from these salts are transformed into secondary copper sulfides (chalcocite and covellite) and even native copper of often high purity, e.g., in the Michigan copper district (Keweenaw Peninsula).

Other metallic elements frequently found in copper ores are iron, lead, zinc, antimony, and arsenic; less common are selenium, tellurium, bismuth, silver, and gold. Substantial enrichments sometimes occur in complex ores. For example, ores from Sudbury, Ontario, in Canada contain nickel and copper in nearly the same concentrations, as well as considerable amounts of platinum metals. The copper ores from Zaire and

Table 6. The most important copper minerals

Mineral	Formula	Copper, wt %	Crystal system	Density, g/cm^3
Native copper	Cu	≦99.92	cubic	8.9
Chalcocite	Cu_2S	79.9	orthorhombic	5.5 – 5.8
Digenite	Cu_9S_5	78.0	cubic	5.6
Covellite	CuS	66.5	hexagonal	4.7
Chalcopyrite	$CuFeS_2$	34.6	tetragonal	4.1 – 4.3
Bornite	Cu_5FeS_4/Cu_3FeS_3	55.5 – 69.7	tetragonal	4.9 – 5.3
Tennantite	$Cu_{12}As_4S_{13}$	42 – 52	cubic	4.4 – 4.8
Tetraedrite	$Cu_{12}Sb_4S_{13}$	30 – 45	cubic	4.6 – 5.1
Enargite	Cu_3AsS_4	48.4	orthorhombic	4.4 – 4.5
Bournonite	$CuPbSbS_3$	13.0	orthorhombic	5.7 – 5.9
Cuprite	Cu_2O	88.8	cubic	6.15
Tenorite	CuO	79.9	monoclinic	6.4
Malachite	$CuCO_3 \cdot Cu(OH)_2$	57.5	monoclinic	4.0
Azurite	$2\,CuCO_3 \cdot Cu(OH)_2$	55.3	monoclinic	3.8
Chrysocolla	$CuSiO_3 \cdot n\,H_2O$	30 – 36	(amorphous)	1.9 – 2.3
Dioptase	$Cu_6\,[Si_6O_{18}] \cdot 6\,H_2O$	40.3	rhombohedral	3.3
Brochantite	$CuSO_4 \cdot 3\,Cu(OH)_2$	56.2	monoclinic	4.0
Antlerite	$CuSO_4 \cdot 2\,Cu(OH)_2$	53.8	orthorhombic	3.9
Chalcanthite	$CuSO_4 \cdot 5\,H_2O$	25.5	triclinic	2.2 – 2.3
Atacamite	$CuCl_2 \cdot 3\,Cu(OH)_2$	59.5	orthorhombic	3.75

Zambia are useful sources of cobalt. Many porphyry copper ores in America contain significant amounts of molybdenum and are the most important single source of rhenium. The extraction of precious metals and other rare elements can be decisive for the profitability of copper mines, smelters, and refineries.

4.2. Origin of Copper Ores

Ore deposits are classified according to their mode of formation, but the origin of copper ores is geologically difficult to unravel, and some of the proposed origins are controversial. The classification distinguishes two main groups, the magmatic series and the sedimentary series.

Magmatic ore formation involves magma crystallization and comprises the following groups:

1) Liquid magmatic ore deposits originate by segregation of the molten mass so that the heavier sulfides (corresponding to matte) separate from the silicates (corresponding to slag) and form intrusive ore bodies. Examples: Sudbury, Ontario; Norilsk, western Siberia.
2) Pegmatitic – pneumatolytic ore deposits develop during the cooling of magma to ca. 374 °C, the critical temperature of water. Examples: Bisbee, Arizona; Cananea, Mexico.
3) Hydrothermal ore deposits result by further cooling of the hot, dilute metal-bearing solutions from ca. 350 °C downward, i.e., below the critical temperature of water. Such deposits contain copper primarily as chalcopyrite and satisfy ca. 50 % of the demand in the Western world. There are many examples of different types of hydrothermal deposits. Examples: Butte, Montana (gangue deposit); Tsumeb, Namibia (metasomatic deposit); Bingham Canyon, Utah; Chuquicamata, Chile; Toquepala, Peru; Bougainville, Solomon Islands (impregnation deposits). Impregnation deposits are also called disseminated copper ores or porphyry copper ores (or simply porphyries) because of their fine particle size.
4) Exhalative sedimentary ore deposits originate from submarine volcanic exhalations and thermal springs that enter into seawater, and constitute a transitional type to sedimentary deposits. These ores are third in economic importance in the Western world. The actual formation of such sulfidic precipitations can be observed, for example, the marine ore slimes in the Red Sea. Examples: Mount Isa, Queensland; Rio Tinto, Spain; Rammelsberg (Harz), Federal Republic of Germany.

The origin of sedimentary ore occurs in the exogenous cycle of rocks and may be subdivided into the following groups:

1) Arid sediments in sandstones and conglomerates occur widely in the former Soviet Union as widespread continental zones of weathering with uneven mineralization. Examples: Dsheskasgan, Kazakhstan; Exótica, Chile.
2) Partly metamorphized sedimentary ores in shales, marls, and dolomites form large strata-bound ore deposits, especially in the African copper belt, and represent the second most important source of copper to the Western world, as well as supplying nearly 75 % of its cobalt. Examples: Zaire (oxidation zone, oxidized ores $\leqq$6 % Cu); Zambia (cementation zone, secondary sulfide ores $\leqq$4 % Cu).
3) Marine precipitates have formed sedimentary ore deposits similar to the present phenomenon of sulfide precipitation by sulfur bacteria in the depths of the Black Sea. Examples: Silesia (copper marl), Poland.
4) Deep-sea concretions lie in abundance on the bottom of the oceans, especially the Pacific Ocean. These so-called *manganese nodules* could also be a source of copper in the future.

4.3. Copper Ore Deposits

Geologically, the main regions of copper ore deposits are found in two formations: the Precambrian shields and the Tertiary fold mountains and archipelagos. There are major producing countries on every continent [38], [39].

North America: United States (Arizona, Utah, New Mexico, Montana, Nevada, and Michigan), Canada (Ontario, Quebec, British Columbia, and Manitoba), and Mexico (Sonora)

South America: Chile, Peru, Argentina, and Brazil

Africa: Zaire, Zambia, Zimbabwe, South Africa, and Namibia

Australia and Oceania: Queensland, Papua New Guinea

Asia: Former Soviet Union (Siberia, Kazakhstan, and Uzbekistan), Japan, Philippines, Indonesia, India, Iran, and Turkey

Europe: Poland (Silesia), Yugoslavia, Portugal, Bulgaria, Sweden, and Finland

Antarctica may be an important source of copper ores in the foreseeable future.

4.4. Copper Resources

World primary copper reserves were estimated in 1991 at 552×10^6 t (Table 7) [41]. Reserves are identified resources and do not include undiscovered resources. With time the available reserves have increased because of technical progress in processing ores with low copper content and the discovery of new ore deposits [38], [39]. About 321×10^6 t were classified as minable copper ores under the technical and economical conditions at that time.

It is believed that a large potential of as-yet untouched deposits exist. Therefore, the potentially usable copper resources are estimated to be about three times as large as the reserve base. In addition to ores on land, there is an estimated amount of copper in deep-sea nodules of about 0.7×10^9 t.

Table 7. Copper ore reserves in 1991 [41]

Country	Ore reserves, 10^6 t	Percentage of world reserves
United States	90	16.3
Chile	120	21.7
Peru	31	5.6
Zambia	30	5.4
Zaire	30	6.3
Canada	23	4.2
Australia	21	3.8
Philippines	16	2.9
Indonesia	8	1.4
China	8	1.4
Poland	15	2.7
CIS	54	9.8
Other countries	106	19.2

If one assumes that total production of primary copper will remain stable, the identified reserves would last until 2040. With an increase in copper production of 2 – 3 %, which is more realistic, the duration of the known reserves will be reduced. However, these forecasts are quite unreliable because the growing use of secondary copper (recycling materials) and the discovery of new copper ore deposits are not considered.

4.5. Mining

Exploration, which is the search for ore deposits and their detailed investigation, is required to

ascertain the commercial feasibility of a potential mine. The used geological, geochemical, or geophysical methods are complicated and expensive. But often legal and political factors are more decisive for a new mine project than technological or financial aspects. The methods used for exhausting the copper ore are depending to a great extent to the type of deposit. Important parameters are metal content of the ore and geometry and depth of the ore body. These parameters determine the working method. Underground and open-cast mining are the two basic techniques. As a generalization mining can be divided into the stages drilling, blasting, loading, and haulage of the ore.

Technological developments like the LHD technique (load, haul, dump) and the use of concrete for stowing have made mining more cost efficient. But underground mining is still more labor-intensive and expensive than open cast mining. Therefore, copper ores with an average Cu content of 1 % or more or that contain other valuable metals in addition to copper (e.g., precious metals, nickel, cobalt) are mined underground, while ores with 0.5 % Cu, which represents a 100-fold enrichment of the average copper content in the earth's crust, are mined by open-cast methods. The porphyry copper deposits which are located near the surface can only be exploited by open-cast technique. They have become more important during the last decades. The first open pit was started at Bingham Canyon early this century. Today the terraced copper open pits are the largest ore mines in the world. They often cover more than one square kilometer and have working depths of several hundred meters. 100 000 t of crude ore are extracted per day. Today more than 50 % of the primary copper comes from open pits. Other less common methods for copper extraction are in situ leaching or ocean mining.

In situ leaching is a hydrometallurgical process in which copper is extracted by chemical dissolution in sulfuric acid. This method is suitable for low-grade copper ore bodies for which customary mining operations would be uneconomical, as well as for the leaching of remenant ores from abandoned mines. In some cases, the ore body must be broken before leaching by blasting with explosives to increase the surface area for chemical reaction.

Ocean mining involves obtaining metalliferous raw materials from the deep oceanic zones. Two groups of substances are of interest: deep-sea nodules [43] and marine ore slimes [44]. The nodules (manganese nodules; see → Manganese and Manganese Alloys, Chap. 9.) contain, in addition to iron oxides, ca. 25 % Mn, 1 % Ni, 0.35 % Co and 0.5 % (max. 1.4 %) Cu. Specially equipped ships have collected and lifted these nodules from depths of 3000 – 5000 m; specific metallurgical and chemical methods for processing the nodules have been developed in pilot plants. Because of the extremely high expenses, large-scale operations of this type have not yet been undertaken. Marine ore slimes from the Red Sea (2200-m depth) average ca. 4 % Zn, 1 % Cu, and a little silver. Although methods for processing these slimes have been investigated, this resource is not now economically important.

5. Production

Over the years copper production methods have been subjected to a continual selection and improvement process because of the need for (1) increased productivity through rationalization, (2) lower energy consumption, (3) increased environmental protection, (4) increased reliability of operation, and (5) improved safety in operation. During this development a number of tendencies have become apparent:

1) Decrease in the number of process steps
2) Preference for continuous processes over batch processes
3) Autogenous operation
4) Use of oxygen or oxygen-enriched air
5) Tendency toward electrometallurgical methods
6) Increased energy concentration per unit of volume and time
7) Electronic automation, measurement, and control
8) Recovery of sulfur for sale or disposal
9) Recovery of valuable byproducts

The selection of a particular production method depends essentially on the type of available raw materials, which is usually ore or concentrate and on the conditions at the plant location.

About 80 % of primary copper production comes from low-grade or poor sulfide ores. After enrichment steps, the copper concentrates are usually treated by pyrometallurgical methods. Generally, copper extraction follows the sequence:

1) Beneficiation by froth flotation of ore to give copper concentrate
2) Optional partial roasting to obtain oxidized material or calcines
3) Two-stage pyrometallurgical extraction
   a) smelting concentrates to matte
   b) converting matte by oxidation to crude (converter or blister) copper
4) Refining the crude copper, usually in two steps
   a) pyrometallurgically to fire-refined copper
   b) electrolytically to high-purity electrolytic copper

Figure 2 [13] illustrates the principal processes for extracting copper from sulfide ore.

About 15 %, with an increasing trend, of the primary copper originates from low-grade oxidized (oxide) or mixed (oxidized and sulfidic) ores. Such materials are generally treated by hydrometallurgical methods.

The very few high-grade or rich copper ores still available can be processed by traditional smelting in a shaft furnace. This process is also used for recovering copper from secondary materials, such as intermediate products, scrap, and wastes.

Figure 3 [13] illustrates the most important operations in copper extraction from various oxidic ores.

5.1. Beneficiation

Sulfidic copper ores are too dilute for direct smelting. Smelting these materials would require too much energy and very large furnace capacities. The copper ore coming from the mine (0.5 – 1 % Cu) must be concentrated by beneficiation. The valuable minerals like chalcopyrite are intergrown with gangue. Therefore, in the first step the lumpy ore is crushed and milled into fine particles ($< 100\,\mu m$) to liberate the individual mineral phases.

Typical equipment for crushing to about 20 cm are gyratory and cone crushers. Then wet grinding in semi-autogenous rod or autogenous ball mills takes place. Size classification takes is performed in cyclones. In the next step of beneficiation, valuable minerals and gangue are separated by froth flotation of the ore pulp, which exploits the different surface properties of the sulfidic copper ore and the gangue [46]. The hydrophobic sulfide particles become attached to the air bubbles, which are stirred into the pulp, rise with them to the surface of the pulp, and are skimmed off as a froth of fine concentrate. The hydrophilic gangue minerals remain in the pulp. Organic reagents with sulfur-containing groups at their polar end, such as xanthates, are used as collectors in the flotation process. Additionally, modifiers like hydroxyl ions (pH adjustment) are used to select different sulfide minerals, for example, chalcopyrite and pyrite. Alcohols are used to stabilize the froth.

To obtain concentrates with highest possible purity and recovery rate, the flotation process usually consists of several stages which are controlled by expert systems. Various sensors for particle size, pH, density, and other properties are installed. Figure 4 gives an overview of a typical beneficiation process at a concentrator. In the first flotation stage, as much copper as possible is recovered in a rougher concentrate so that as little as possible goes to the tailings. To increase the copper recovery rate, often these tailings are leached with sulfuric acid. After regrinding, the rough concentrate is cleaned in several flotation steps. After sedimentation in thickeners and filtration in automatic filter presses or vacuum filters (ceramic disk) the typical copper concentrate contains 25 – 35 % Cu and about 8 % moisture. The moisture content of the concentrate is a compromise between transporting water (cost) and avoiding dust generation during transport. Dewatered concentrates may heat spontaneously or even catch fire; therefore, appropriate precautions must be taken [47].

Copper concentrators typically treat up to 100 000 t of ore per day. They are located directly at the mines to achieve low transport costs. The copper recovery efficiency is over 90 %. About 95 % of the ore input goes into the tailings, which are stored in large dams near the mine and are used for water recycling to the flotation stages.

Separation of special copper ores such as those containing molybdenite or with high zinc

Figure 2. Principal processes for extracting copper from sulfide ore

Figure 3. Principal processes for extracting copper from oxidic ore [45]

Figure 4. Overview of a typical beneficiation process at a concentrator

or lead content (Canada) is also possible by flotation methods. Flotation of non-sulfide copper minerals is rare because these ores are mostly subjected to hydrometallurgical copper recovery, for example, heap leaching. In Zambia and Zaire, however, siliceous copper oxide ores are floated with fatty acid collectors, and dolomitic copper oxide ores are sulfidized with sodium hydrogensulfide and then floated [48].

5.2. Roasting

Roasting can be used to prepare sulfide concentrates for subsequent pyrometallurgical or hydrometallurgical process. Partial roasting under oxidizing conditions may be carried out prior to smelting in reverberatory or electric furnaces. Complete oxidizing or sulfatizing roasting may be performed before leaching operations, especially if other valuable metals such as cobalt are present in the concentrate. Reducing roasting may be carried out if copper concentrates with very high contents of impurities such as As are to be smelted.

However, roasting processes are today not very important for the copper extraction process. Only a few plants are still operating, for example Boliden's Rönnskär Smelter [211] and Bor Smelter [212]. Since ca. 1975 combined roasting and matte smelting processes such as flash smelting have been favored because of their lower energy consumption and process gas handling advantages.

The roasting process has several effects:

1) Drying the concentrates
2) Oxidizing a part of the iron present
3) Controlling the sulfur content
4) Partially removing volatile impurities, especially arsenic
5) Preheating the calcined feed with added fluxes, chiefly silica and limestone

Chemical Reactions. When the moist concentrates, which contain many impurity elements, are heated, a multitude of chemical reactions occur. Because analysis of the many thermodynamic equilibria is not practical, a few fundamental systems are usually chosen. The most important is the ternary copper – oxygen – sulfur system (Fig. 5). The next most important system is the ternary iron – oxygen – sulfur system because most sulfidic copper ores contain significant amounts of iron.

Initially, sulfides such as pyrite and chalcopyrite decompose and generate sulfur vapor, which reacts with oxygen to form sulfur dioxide:

$$FeS_2 \longrightarrow FeS + S(g)$$

$$2\,CuFeS_2 \longrightarrow Cu_2S + 2\,FeS + S(g)$$

$$S(g) + O_2(g) \longrightarrow SO_2(g)$$

The principal reactions, i.e., the formation of metal oxides, sulfur trioxide, and metal sulfates, are exothermic.

$$MS + 1.5\,O_2 \rightleftharpoons MO + SO_2$$

$$SO_2 + 0.5\,O_2 \rightleftharpoons SO_3$$

$$MO + SO_3 \rightleftharpoons MSO_4$$

In addition, there are secondary reactions, such as the formation of basic sulfates, ferrites (especially magnetite), and silicates, the last providing most of the slag in the subsequent smelting:

$$MO + MSO_4 \longrightarrow MO \cdot MSO_4$$

$$MO + Fe_2O_3 \longrightarrow MFe_2O_4$$

$$FeO + Fe_2O_3 \longrightarrow Fe_3O_4$$

$$MO + SiO_2 \longrightarrow MSiO_3$$

Representative reductive roasting reactions are:

$$FeS_2 \longrightarrow FeS + S(g)$$

$$8\,FeAsS \longrightarrow 4\,FeAs + 4\,FeS + As_4S_4(g)$$

Figure 5. Partial phase diagram of the ternary Cu – O – S system [51]

Methods. There are several important roasting methods; all involve oxidation at an elevated temperature, generally between 500 and 750 °C:

1) *Partial (oxidizing) roasting* is the conventional way of extracting copper from sulfide concentrates. At 700 – 750 °C, the degree of roasting is determined by controlling the access of air. A predetermined amount of sulfur (30 – 50 % is removed, and only part of the iron sulfide is oxidized. The copper sulfide is relatively unchanged. These conditions are important for the formation of a suitable matte.
2) *Total, or dead, roasting* is occasionally used for complete oxidation of all sulfides for a subsequent reduction process or for special hydrometallurgical operations.
3) *Sulfatizing roasting* is carried out at 550 – 650 °C to form sulfates. This method yields calcines well-suited for hydrometallurgical treatment.

Roasters. Industrial roasting is done in two types of roasters: fluidized-bed and multiple-hearth roasters. Both are continuously operated processes.

Oxidizing roasting is usually carried out in fluidized-bed roasters with short residence times in the range of seconds and high production rates up to 50 t of moist concentrate per hour. The oxidation reactions supply most of the required heat. About 30 – 50 % of the incoming sulfide is oxidized to SO_2 by using slightly oxygen enriched air (up to 30 % O_2). The off-gas is rich in SO_2(6 – 12 %) and suitable for conversion to sulfuric acid. The hot calcine is usually sent to reverberatory or electric furnace. The advantage of a roaster in front of a smelting furnace is the lower energy requirement of the smelting furnace and the higher matte grade. Examples of fluidized-bed roasters are Boliden Rönnskär (Sweden), Bor Smelter (Yugoslavia) in front of pyrometallurgical copper extraction, and Chambishi (Zambia) ahead of a leaching plant.

Reductive roasting is usually carried out in multiple-hearth furnaces because of the long residence time (several hours) and the precise control of temperature and gas composition on each hearth. These roasters have lower production rates and are fired by natural gas burners. An example for the reducing process is the treatment

of El Indio (Chile) concentrate, which contains 8 % As and about 22 % Cu. About 97 % of the arsenic is removed during the roasting process at about 650 – 720 °C [213]. In former times the multiple-hearth roasters (Herreshoff furnaces) were widely used for the extraction of copper from concentrates.

5.3. Pyrometallurgical Principles

Smelting of unroasted or partially roasted sulfide ore concentrates produces two immiscible molten phases: a heavier sulfide phase containing most of the copper, the *matte*, and an oxide phase, the *slag*. In most copper extraction processes, matte is an intermediate.

5.3.1. Behavior of the Components

The most important equilibrium in copper matte smelting is that between the oxides and sulfides of copper and iron:

$$Cu_2O + FeS \rightleftharpoons Cu_2S + FeO$$

Iron(II) oxide [*1345-25-1*] reacts with added silica flux to form fayalite [*13918-37-1*], a ferrous silicate that is the main component of slag:

$$2\,FeO + SiO_2 \longrightarrow Fe_2SiO_4$$

Liquid iron sulfide [*1317-37-9*] reduces higher iron oxides to iron(II) oxide:

$$3\,Fe_2O_3 + FeS \longrightarrow 7\,FeO + SO_2(g)$$

$$3\,Fe_3O_4 + FeS \longrightarrow 10\,FeO + SO_2(g)$$

The second reaction serves to remove magnetite [*1309-38-2*], which complicates furnace operations because of its high melting point (1590 °C) [54].

The pyrometallurgical production of copper from sulfide ore concentrates may be considered as a rough separation of the three main elements as crude copper, iron(II) silicate slag, and sulfur dioxide. About 20 accompanying elements must be removed from the copper by subsequent refining. Table 8 shows the distribution of important impurities among matte, slag, and flue dust. Precious metals, such as silver, gold, platinum, and palladium, collect almost entirely in the matte, whereas calcium, magnesium, and aluminum go into the slag.

Table 8. Average percentage distribution of the accompanying elements in copper smelting, p. 591[20]

Element	Matte	Slag	Flue dust
Arsenic	35	55	10
Antimony	30	55	15
Bismuth	10	10	80
Selenium	40	–	60
Tellurium	40	–	60
Nickel	98	2	–
Cobalt	95	5	–
Lead	30	10	60
Zinc	40	50	10
Tin	10	50	40
Silver and gold	99	1	–

5.3.2. Matte

The ternary Cu – Fe – S system is discussed in detail in the literature [55–57]. Figure 6 shows the composition of the pyrometallurgically important copper mattes and the liquid-phase immiscibility gap between matte and the metallic phase. In the liquid state, copper matte is essentially a homogeneous mixture of copper(I) and iron(II) sulfides: the pseudobinary Cu_2S – FeS system.

Arsenides and antimonides are soluble in molten matte, but their solubility decreases with an increasing percentage of copper in the matte. Accordingly, when the arsenic concentration is high, a special phase, the so-called *speiss*, can separate. It is produced under reducing conditions in the blast or electric furnace, and its decomposition is complicated (→ Arsenic and Arsenic Compounds, → Antimony and Antimony Compounds).

Compositions of several copper mattes are shown in the partial diagram Cu_2S – FeS – (Fe_3O_4 + FeO) (Fig. 7), which is a section of the quaternary Cu – Fe – O – S system. The density of solid copper mattes ranges between 4.8 g/cm^3 (FeS) and 5.8 g/cm^3 (Cu_2S); liquid mattes have the following densities: 4.1 g/cm^3 (30 wt % Cu, 40 wt % Fe, 30 wt % S), 4.6 g/cm^3 (50 wt % Cu, 24 wt % Fe, 26 wt % S), and 5.2 g/cm^3 (80 wt % Cu, 20 wt % S).

Figure 6. Ternary Cu – Fe – S diagram showing copper mattes and the miscibility gap [55]

Table 9. Composition (wt %) of typical copper smelter slags [64]

Component	Reverberatory furnace	Flash furnace	Noranda reactor	Peirce – Smith converter
Copper	0.4 – 0.6	1 – 2	8 – 10	2 – 8
Iron (total)	35	40	35	50
Silica	38	30	21	25
Magnetite	7 – 12	13	25 – 29	20 – 25
Ratio of Fe to SiO_2	0.92	1.33	1.67	2.0

5.3.3. Slags

Slags from copper matte smelting contain 30 – 40 % iron in the form of oxides and about the same percentage of silica (SiO_2), mostly as iron(II) silicate. Such slags can be considered as complex oxides in the $CaO - FeO - SiO_2$ system [59] or, because of the relatively low CaO content of most slags, in the partial diagram $FeO - Fe_2O_3 - SiO_2$ [60] (Fig. 8). Ternary systems of these and other pertinent oxide systems are found in the literature [61], [62]. Table 9 shows the general composition of some slag types. Important properties of copper slag systems are compiled in [63].

Figure 8. Ternary $FeO - Fe_2O_3 - SiO_2$ diagram [60]

The objectives of matte smelting are to achieve a rapid, complete *separation of matte*

and slag, the two immiscible phases, and a minimal copper content in the slag. The differing properties of slag and matte affect this separation:

1) the low, narrow melting interval of slag
2) the low density of liquid slag (ca. 3.1 – 3.6 g/cm^3) and the difference in density between molten matte and slag of ca. 1 g/cm^3
3) the low viscosity and high surface tension of the slag

The ratio of the weight percent of copper in matte to that of copper in slag should be between 50 and 100. High matte grades generally cause high copper losses in slag. Such losses depend on the mass ratio of slag to copper produced, which is usually between 2 and 3. Copper in slags occurs in various forms, including suspended matte, dissolved copper(I) sulfide, and slagged copper(I) oxide, partially as a silicate, which is typical of nonequilibrium processing.

Slags containing < 0.8 % copper are sold as products with properties similar to those of natural basalt (crystalline) or obsidian (amorphous) or discarded as waste. When liquid slag is cooled slowly, it forms a dense, hard, crystalline product that can be used as a large-size fill for riverbank protection or dike construction and as a medium-size crushed fill for roadbeds or railway ballast. Quick solidification, by pouring molten slag into water, gives amorphous granulated slag, an excellent abrasive that has partially supplanted quartz sand. Ground granulated slag is used as a trace element fertilizer because of its copper and other nonferrous metals.

Most of the newer copper smelting processes produce high-grade mattes, and the short residence time of the materials in the reaction chamber results in an incomplete approach to chemical equilibrium. Both factors lead to high amounts of copper in the slag, generally >1 wt %. Such slags must be treated by special methods for copper recovery (Section 5.5.1).

5.3.4. Oxidizing Smelting Processes

Nearly all pyrometallurgical copper processes are based on the principle of partial oxidation of the sulfide ore concentrates. Methods based on the total oxidation of sulfide ores with subsequent reduction to metal, avoiding the formation of copper matte, are used only rarely because of high fuel consumption, formation of copper-rich slags, and production of crude copper with a high level of impurities.

Prior to the 1960s, the most important way of producing copper was roasting sulfide concentrates, smelting the calcines in reverberatory furnaces, and converting the matte in Peirce – Smith converters. Since that time, the modern flash smelting process with subsequent converting has become predominant. Figure 9 shows the flow sheet of a modern copper smelter, from concentrate to pure cathode copper, including the use of oxygen, recovery of waste heat, and environmental protection. Table 10 compares the important stages and processes of copper production, showing the range of the matte composition for each process.

Figure 9. Typical flow sheet for pyrometallurgical copper production from ore concentrates [65]

5.3.5. Proposals

Numerous laboratory experiments and pilot-plant runs have been carried out to develop smelting methods based on elements other than

oxygen. Two lines of development have dominated, reduction with hydrogen and chlorination, but without leading to commercialization.

Reduction. A potential process involves the reduction of chalcopyrite [70]:

$$2\,CuFeS_2 + 3\,H_2 + 3\,CaO \longrightarrow Cu_2S + 2\,Fe + 3\,CaS + 3\,H_2O$$

$$CuFeS_2 + 2\,H_2 + 2\,CaO \longrightarrow Cu + Fe + 2\,CaS + 2\,H_2O$$

The reduction by hydrogen is endothermic, but the overall reaction with calcium oxide is exothermic. A similar proposal [71] is based on the reaction of a metal sulfide with steam in the presence of calcium oxide:

$$\begin{array}{l} MS + H_2O \longrightarrow MO + H_2S \\ H_2S + CaO \longrightarrow CaS + H_2O \\ \hline MS + CaO \longrightarrow CaS + MO \end{array}$$

Chlorination. The reactions of chalcopyrite with chlorine are also of interest [72]:

$>500\,°C$:

$$CuFeS_2 + 2\,Cl_2 \longrightarrow CuCl_2 + FeCl_2 + 2\,S$$

$<500\,°C$:

$$CuFeS_2 + 3.5\,Cl_2 \longrightarrow CuCl_2 + FeCl_3 + S_2Cl_2$$

followed by electrolysis of the molten copper (I) chloride.

The recently proposed thermoelectron chlorination process is another variation [73]:

$$CuFeS_2 + 2\,Cl_2 \longrightarrow CuCl + FeCl_3 + 2\,S$$

Electrolysis. Another approach, to avoid converting, proposed the electrolysis of molten copper matte [74].

5.4. Traditional Bath Smelting

At the end of the Middle Ages, copper was produced by the German or Swedish smelting process that involved roasting reduction with up to seven process steps in small shaft furnaces. Around 1700, reverberatory furnaces were constructed in which the ore was processed by roasting, the so-called English or Welsh copper smelting process, originally with ten process steps.

The large blast and reverberatory furnaces of the 1900s were derived from these principles. Later, the electric furnace for matte smelting was developed. Newer processes are the Isasmelt/Ausmelt/Csiromelt (furnace with vertical blowing lance), the Noranda and CMT/Teniente reactors (developed from converters), the Russian Vanyukov, and the Chinese Bayia process.

5.4.1. Blast Furnace Smelting

The blast or shaft furnace is well-suited for smelting high-grade, lumpy copper ore. If only fine concentrates are available, they must first be agglomerated by briquetting, pelletizing, or sintering. Because of this additional step and its overall low efficiency, the blast furnace lost its importance for primary copper production and is currently used in only a few places, for example, Glogow in Poland.

Smaller types of blast furnace, however, are used to process such copper-containing materials as intermediate products (e.g., cement copper or copper(I) oxide precipitates), reverts (e.g., converter slag, refining slag, or flue dusts), and copper-alloy scrap.

The construction of the furnace is basically related to that of the iron blast furnace, but there are considerable differences in design, especially in size and shape: the copper blast furnace is lower and smaller, and its cross section is rectangular. Developments adopted from the steel industry include use of preheated air (hot blast), oxygen-enriched air, and injection of liquid fuels.

The furnace is charged with alternate additions of *mixture* (copper-containing materials and accessory fluxes such as silica, limestone, and dolomite) and coke (which serves as both fuel and reducing agent). There are three zones in the furnace:

1) In the heating zone (the uppermost), water evaporates and less stable substances dissociate.
2) In the reduction zone, heterogeneous reactions between gases and the solid charge take place.

3) In the smelting zone, liquid phases react.

The usual mode of operation is *reducing smelting*, which yields two main products. Sulfide ores are used to produce a matte (40 – 50 wt % Cu) and a disposal slag (ca. 0.5 wt % Cu). In contrast, oxide ores are processed directly to impure black copper (≦95 wt % Cu) and to a copper-rich slag. The two ore types can be smelted together to produce matte and a slag with low copper content. Another product is top gas, which contains flue dust. Ores that contain high concentrations of arsenic and antimony also form speiss, which is difficult to decompose.

In Poland (KGHM Polska Meidz S.A. Smelters in Glogow I and Legnica) the blast-furnace technology is well adapted to Polish copper concentrates, which contain about 20 – 30 % Cu like normal chalcopyrites but also 5 – 10 % of organic carbon and only 9 – 12 % S. Also these concentrates have relatively high lead (up to 2.5 %) and arsenic (up to 0.3 %) content. The organic carbon compounds provide about 40 – 60 % of the process energy; the rest is added by coke. The matte has about 58 – 63 % Cu and 3 – 6 % Pb. The slag contains less than 0.5 % Cu. The off-gas from the blast furnaces (three in each plant) is mixed with the converter gases (Hoboken Converter). It contains 7 – 10 % SO_2 and is sent to sulfuric acid production. The production figures are 80 000 t/a converter copper in Legnica, and 200 000 t/a in Glogow I Smelter [214].

5.4.2. Reverberatory Furnace Smelting

The reverberatory furnace dominated copper matte smelting for much of the 1900s, because it was an excellent process for smelting fine concentrate from flotation. It is a fossil fuel fired hearth furnace for smelting concentrate and producing copper matte. The reverbs began to decline in the 1970s with the adoption of environmentally and energetically superior processes like flash smelting. Probably the last one was erected in 1976 in Sar Chemesh, Iran. In 1980 about 100 reverbs were in operation, but in 1994 the number had decreased to about 25. As shown in Figure 10 it is a rectangular furnace up to 10 m wide and 35 m long with internal brick lining. Throughputs of up to 1100 t/d concentrate or a mixture of concentrate and calcine could be processed. The charge is passed into the furnace near the burners through the roof or lateral openings. As fossil fuel, pulverized coal, heavy oil, or natural gas is used. Normally the burner is located in the front wall of the furnace. The atmosphere is slightly oxidizing, and the maximum flame temperature is up to 1500 °C. During the 1980s oxygen – fuel burners have been set in the roof to fire downwards directly on the top of the bath. This increases the smelting rate by up to 40 % and the energy efficiency to about 50 % [76], [215]. Another invention was the sprinkler burner for feeding concentrate, coal, and flux from the top of the reverb [77].

The back half of the furnace is the settling zone. A matte grade of between 35 and 60 % Cu is produced, depending on whether concentrate or calcine is fed. The slag has low copper content (< 1 %). Normally, the converter slag is also fed back to the reverb. Sometimes problems with solid magnetite accretions in the furnace occur.

The off-gas has a temperature of about 1250 °C. It is diluted by the combustion air and contains only about 1 – 2 % SO_2. This is too low for efficient SO_2 capture such as sulfuric acid production by the contact process. Improvements have been achieved by using higher oxygen enrichment of the burners, but the off-gas is still too dilute, and therefore this furnace is unsuitable for many regions in the world because of environmental problems. Another disadvantage is the very high energy consumption. The reverb has the highest energy consumption of all copper matte smelting processes. A good present example for operating reverbs is the Ilo Smelter in Peru (Table 11). There two reverbs smelt about 2000 t/d of concentrate, producing a matte containing 35 % copper for the subsequent Peirce – Smith converters. In the latest smelter enlargement one reverb was replaced by an Teniente converter (CMT), and a sulfuric acid plant for partial SO_2 recovery was built.

5.4.3. Electric Furnace Smelting

In regions where relatively cheap electrical power was available, electric furnaces were built. The Scandinavian countries were the first to perform electric matte smelting: 1929 at Sulitjelma, Norway; 1938 at Imatra, Finland, and

Figure 10. Schematic longitudinal and cross-section views through a reverberatory furnace [45]

1949 at Rönnskär, Sweden, which is still operating.

Electric furnaces have the rectangular ground plan and the dimensions of larger reverberatory furnaces. Along the centerline, up to six Söderberg continuous self-baking electrodes are used with alternating current (Table 11).

Table 11. Examples of traditional reverberatory and electric furnaces

	Boliden Rönnskär Smelter	Southern Peru Ilo Smelter
Type	electric furnace	reverbatory
Inside dimensions $l \times w \times h$, m	$24 \times 6 \times 3$	$36 \times 10 \times 3.4$
Electrodes/burners	6	8
Smelting capacity, t/d	950 (hot calcine)	1000 (wet concentrate)
Matte grade, % Cu	51	35
Off-gas volume, m^3/h (STP)	25 000	100 000
SO_2 content, %	4.5	1.2
Energy consumption	300 kW/t concentrate	194 kg oil/t concentrate

The smelting process in such units is similar to the operation in reverbs, but the concentrate is usually dried and roasted before charging to increase the smelting capacity. The converter slag is returned to the furnace. The composition of matte and slag resembles that of the reverb products, but the content of magnetite is lower. No fuel is burned, and the volume of waste gases and the quantity of flue dust are small. The SO_2 content of the waste gas can be 10 %. The off-gas also contains carbon oxides from the consumption of the graphite electrodes.

A significant difference between the electric furnace and the reverb is the inversion of the temperature gradient in the furnace cavity. In the reverb, the combustion gases have the highest temperature, whereas in electric matte smelting, the waste gases are ca. 500 °C cooler than the slag phase, which is heated by the electric energy. Accordingly, in the electric furnace, cheap refractories are sufficient for lining the walls above the slag zone and the roof; only a common arch is required.

The temperatures of both molten phases depend on the submergence of the electrodes, and the required heat is controlled by the electrical power supplied. Heat transfer takes place chiefly by convection, which causes intense circulation in the molten bath.

The current is divided into two partial circuits, through slag and through matte. The difference in conductivity is great, slag : matte ratio of $1 : 10^2$ to $1 : 10^3$; therefore, the depth of immersion of the electrodes into the liquid slag must be precisely controlled. As the electrodes immerse deeper into the slag, more current flows through the matte. If they touch the matte layer, a short circuit occurs. These considerations lead to an approximate relation between the electrical power input and the depth of the slag layer: 6000 kVA and 0.5 m, 30 000 kW and 1.0 m, and 50 000 kW and 1.5 m.

The smelting capacity of electrical furnaces is higher than that of reverbs.

Brixlegg Process. Lurgi developed and practiced at Brixlegg, Tirol, Austria, a modification of the old roasting reaction process. Nearly dead-roasted concentrates are reduced in batches by coal in a small special circular electric furnace (2500 kVA, 5-m diameter). The crude copper averaged only 95 wt % Cu, and the operation has been discontinued.

5.4.4. Isasmelt Furnace

The Isasmelt furnace and the closely related Ausmelt furnace were both developed in the 1980s on the basis of work conducted by CSIRO, Australia [216]. The process consists of a tall cylindrical furnace (small diameter but large height, internally brick lined) equipped with a vertical blowing lance. The lance is submerged into the bath (slag) and blows oxygen-enriched air and/or fossil fuel (natural gas). The moist concentrate and flux material is pelletized and fed through the roof of the furnace onto the bath. Most of the energy requirement comes from the reaction of the concentrate. The lance is made from stainless steel. It is cooled by swirling the air in the annulus between the pipes so that a protective layer freezes on that part of the lance which is immersed in the slag bath (0.3 m) [217]. The lance has to be replaced from time to time, for example, once a week. In the continuous Isas process, an emulsion of matte and slag is produced, which is tapped periodically to a electric or fuel-fired settling furnace for matte/slag separation. The off-gas is high in SO_2. For cooling it passes through a waste-heat boiler.

Two Isasmelter for copper matte are running (Mount Isa, Australia; Cypus Miami, Arizona). Figure 11 shows the Cyprus furnace schematically. About 90 t/h of copper concentrate is processed, and about 45 t/h of matte is produced (58 % Cu). The off-gas contains about 35 % SO_2 directly behind the furnace and is then diluted by air to 8 – 9 %. The Isasmelt process has replaced the electric (reverberatory) furnace, which is now used for matte/slag settling. Smaller Isasmelt or Ausmelt furnaces have also been proposed or built for secondary copper smelters and primary smelters like in China. It is possible to run the process batchwise, smelting and converting the material in the furnace for producing blister copper. Also Isasmelt furnaces have been built for lead refining.

5.4.5. Noranda Process

The Noranda process was initially constructed as a continuous smelting and converting process which produced blister copper from copper concentrate. The first reactor was built in 1973 at Horne smelter [105]. This direct-to-blister process operated from 1973 to 1975 [218]. It was switched to high-grade copper matte smelting (as it now still operates) because of excessive impurity levels in the copper anodes and to increase the smelting rate.

Figure 11. Isasmelt furnace

The Noranda furnace [219] is a horizontal steel barrel with an inner brick lining (Figure 12. The diameter is about 5 m and it is about 20 m long. The process runs continuously. At one end of the reactor, pelletized wet concentrate, coal, flux, revert materials, and scrap are thrown into the furnace and on to the top of the molten bath by a high-speed slinger belt. Feeding fine concentrate through the tuyeres is also possible. The feed material is absorbed and melted in the liquid matte/slag bath. On the side there are 20 – 40 tuyeres in the cylindrical part of the vessel. Oxygen-enriched air (ca. 40 % O_2) is blown through these tuyeres into the matte phase. The tuyeres have to be punched periodically, as in a Peirce – Smith converter. A layer of matte and slag must always be present in the furnace.

The oxidation reaction of the sulfides (mostly iron sulfide) and the added coal provide the process energy. Matte is tapped at the bottom of the vessel. Slag is periodically tapped at the

other end of the cylindrical furnace where there are no tuyeres and the bath is quiet enough for matte and slag settling. The matte usually contains 70 – 75 % Cu (white metal) and is sent to a subsequent converter. This operation gives a large heat evolution from Fe and S oxidation in the Noranda furnace. This avoids excessive retention of impurities like Sb in the matte. The slag contains about 3 – 7 % copper and goes to further treatment like electric furnace or solidification/comminution/flotation. The off-gas contains about 15 – 20 % SO_2. It passes through the large mouth at the top of the reactor into a hood and is sent to cooling, cleaning, and sulfuric acid production. In case of emergencies the furnace can be rolled out so that the tuyeres have a secure position above the molten bath.

Figure 12. Noranda furnace

The Noranda process is well suited for smelting scrap and residues, ashes, precious metals scrap, telephone scrap, and computer/electronic scrap. Due to the high temperature and smelting intensity, potentially harmful organics are oxidized to CO_2 and H_2O. The productivity can be increased by using higher oxygen enrichment. Then less fossil fuel is needed and the amount of off-gas decreases.

5.4.6. CMT/Teniente Process

The Caletones Matte Treatment (CMT) or so called Teniente process [220], [221] is similar to the Noranda process. The important differences are that no coal is included in the charge and molten low-grade copper matte is periodically added as fuel. Therefore, the Teniente furnace is mostly regarded as a converter.

The process was developed at Teniente Smelter by adding dry concentrate to a Peirce – Smith converter for increasing existing smelter capacity. The Teniente process has been widely adopted in Latin America. Like the Noranda reactor, it is a robust technology but has still not demonstrated that it can meet the highest environmental standards. The furnaces are horizontal cylinders, 4 – 5 m in diameter and 14 – 22 m long (Figure 13). Inside, the converter is brick-lined, and it has 30 – 50 tuyeres for blowing oxygen-enriched air (30 – 32 % O_2). Solid feed such as wet concentrate, flux, or recycled materials are blown continuously through a high-pressure gun (Garr gun) on the top of the molten bath. Dry concentrate is injected additionally through four or five tuyeres in the bath. Molten matte (35 – 40 % Cu) coming from a reverb is added periodically through the mouth of the converter. The temperature in the converter is controlled by the ratio of wet (lowers temperature) and dry (increases temperature) feed material.

High-grade matte (72 – 77 % Cu) is produced and tapped periodically to the subsequent converting step. Slag with 4 – 7 % Cu is tapped for further processing. The off-gas is collected by a water-cooled hood above the mouth of the converter. The off-gas is mixed with air because the hood is not tight to the converters mouth. Therefore, the SO_2 content is only about 10 %. The gas is cooled with water sprays, the flue dust is stripped and then the gas is sent to sulfuric acid production (or in some cases to the stack).

With its molten-matte requirement, the CMT is dependent on the operation of a reverberatory furnace with all the associated environmental problems (SO_2 emission). To overcome this reliance, some possibilities have been tested, all of which increase the energy in the vessel: increased oxygen enrichment of the blast, increased injection of dry concentrate through the tuyeres, and burning small amounts of fossil fuel. Today there are CMTs which do not need low-grade molten matte.

5.4.7. Vanyukov Process

The Vanyukov process was developed in the 1970s in Norilsk, Russia. It is similar to the Noranda process, but the furnace is rectangular with tuyeres on both sides, blowing highly enriched air (70 – 90 % O_2) in the slag zone (Figure 14).

Figure 13. Teniente converter (CMT)

Moist copper concentrate is charged through ports in the roof of the furnace. The process produces matte (ca. 50 % Cu), slag (1.5 – 2 % Cu) and off-gas (ca. 30 % SO_2). The furnace operates continuously, and the matte and slag leave the furnace continuously through two siphons. The matte is sent to converting process, and the slag is cleaned in an electric furnace [222], [223].

In contrast to the Noranda furnace the Vanyukov reactor is stationary. The tuyeres can not be tilted out of the bath in emergency situations. The advantage of the stationary system is the simple and very efficient SO_2 capture. Six Vanyukov furnaces are running in the CIS. With a relatively small furnace (10 m long, 2 m wide, and 6 m high) about 1500 to 2000 t/d concentrate can be processed.

All the submerged-tuyere processes like Noranda, CMT, and Vanyukov have relatively short campaign lifetimes (one year) because of high erosion in the tuyere zone.

5.4.8. Baiyin Process

At the Baiyin Copper Smelter in China, a process similar to the Noranda furnace was developed in the 1980s [78]. Concentrate is added on the top of the molten bath, and air/oxygen is blown through submerged tuyeres into the melt. The Baiyin furnace has a wall inside to divide the reaction and the settling zone. In China there are at least two furnaces in operation, but few data are available.

5.5. Autogenous Smelting

Autogenous smelting involves the use of combustion heat generated by reactions of the feed in an oxidizing atmosphere in which the sulfide concentrate acts partly as a fuel. The formerly separate steps of roasting and smelting are combined into a roast – smelting process. The spatial and temporal coupling of exothermic and endothermic reactions leads to an economical process, but the sensible heat of nitrogen in the air causes a deficit in the heat balance. In practice, various measures must be taken:

1) Increasing the oxygen content of the combustion air and even using pure oxygen
2) Preheating combustion air with waste heat or in a preheater
3) Combustion of natural gas, fuel oil, or pulverized coal in supplementary burners

To achieve autogenous operation and prevent agglomeration of the feed, the moisture in the concentrate must be removed by drying before charging. The quantity of added fluxes is minimized as far as practical to save energy.

Because the residence time of the sulfide particles in the reaction chamber is only a few seconds, kinetic conditions predominate over the thermodynamic equilibrium. The reactants form a heterogeneous system, with the feed suspended in the gas flow, thus the term *smelting in suspension.*

These processes have several advantages:

1) High rate of reaction, increasing the production rate
2) Energy savings

Figure 14. Vanyukov furnace

3) Low volume of off-gas and correspondingly high concentration of SO_2 and low quantity of flue dust, if oxygen is used

However, a typical disadvantage is the high copper content of the slags, and the relatively high flue dust content in the off-gas, which can cause problem in the waste-heat boiler.

5.5.1. Outokumpu Flash Smelting

After a preliminary test in 1946, the first full-scale flash smelting furnace started operation in 1949 at Outokumpu Oy, Harjavalta (Finland). Flash smelting has been the most widely adopted copper matte smelting process since 1970. More than 40 furnaces have been installed to replace reverberatory furnaces or at new smelting operations. Nowadays the Outokumpu-type smelters account for more than 50 % of world primary smelter capacity.

Furnace Design. The flash furnace can be envisioned as a combination of a reverb with a roaster in which smelting takes place simultaneously. Figure 15 shows a Outokumpu flash furnace designed in 1988 for smelting more than 3000 t/d of copper concentrate – a production rate several times higher than those of earlier furnaces. The current trend is towards even bigger units. The furnace is 24 m long, 7.5 m wide, and 2 m high in the settling area. The hearth or settler is equipped with oil or natural gas burners.

The reaction shaft is 6 m in diameter and 7 m in height. It is equipped with one concentrate burner. The gas off-take shaft is 9 m high and has a diameter of 5 m. (All dimensions inside the furnace, which is lined with chrome magnesia bricks.) The furnace has eight matte tapholes and four slag tapholes. The reaction shaft and large areas of the settler and the gas off take are water-cooled to prevent overheating and weakening of the furnace structure. The reaction shaft of many furnaces is cooled by cascading water outside the steel shell. The other areas are usually cooled by special copper cooling jackets, which are built into the furnace walls [224].

Figure 15. Outokumpu flash smelting furnace

An important feature of the flash smelter is the concentrate burner, which suspends the feed particles in the oxygen-enriched air in the hot reaction shaft. The aim is to ensure a rapid, uniform (over the shaft, to prevent hot spots), and efficient concentrate oxidation and generate minimum flue dust. Older flash smelters have four burners, but nowadays a single burner is used because it is easier to control the burner parameters. The burner (Fig. 16) consists of two concentric pipes: a central pipe for the solid feed and an annulus for the oxygen-enriched blast. In the inner pipe a distributor cone is installed to optimize the particle distribution [225]. The gas velocity out of the burner is up to 200 m/s.

Figure 16. Schematic of a flash furnace concentrate burner

Flash furnaces need auxiliary equipment like solids dryers (rotary, flash, or steam dryers), delivery systems, oxygen plant, blower and preheater systems, waste-heat boiler, dust recovery and recycling system, slag-treatment furnace, and sulfuric acid plant for treating the highly SO_2 enriched off-gas.

Operation. Various sorts of concentrate and a few flux materials (mainly silica) are blended and then dried before feeding into the flash smelter. Recycle materials such as flue dust from the waste-heat boiler and the converters or others are also fed to the flash furnace. The process operates continuously 24 h a day, and campaigns are run for as long as possible with out interruption.

The feed mixture is suspended at the top of the reaction shaft, and sulfur and iron are oxidized partly. The reactions are strongly exothermic, and the particles melt to form copper matte and slag. At oxygen enrichments of between 45 and 80 % (depending on concentrate composition and preheated blast), the process runs autothermally. Less oxygen enrichment requires fossil fuel combustion in the reaction shaft. The temperature in the reaction shaft is about 1250 – 1300 °C. The optimal matte concentration is between 60 and 65 % Cu. Higher Cu concentrations the in the matte are also possible, for example, before a flash converting process.

The matte is tapped as needed by the subsequent converting step. Slag is tapped nearly continuously. The slag contains 1 – 2 % of copper, mainly in matte droplets. The slag temperature is about 1230 – 1250 °C; the matte is about 30 – 50 °C cooler. Typical operating data are shown in Table 12.

Table 12. Operating data for Outokumpu flash furnaces

	Norddeutsche Affinerie, Hamburg, Germany	BHP Magma Metals, San Manuel, Arizona
Furnace commissioning date	1972	1988
Size, inside brick, m hearth $w \times l \times h$	$6 \times 20 \times 3$	$7.5 \times 24 \times 2$
reaction shaft $d \times h$	6×9	6×6.9
Concentrate throughput, t/d	2000 (30 – 34 % Cu)	3000 (30 % Cu)
Blast temperature, °C	400 – 420	25
Oxygen enrichment, %	45 – 55	60 – 80
Blast flow-rate, m^3/h (STP)	25 000	51 000
Matte grade, % Cu	63	63
Off-gas volume, m^3/h (STP)	55 000	55 000
SO_2 Content	25 – 30	35
Recycling of converter slag	in flash furnace	flotation
Slag treatment	electric furnace	flotation
Fossil fuel input in shaft	0	0
Fossil fuel for settler burner	5 m^3/h (STP) natural gas/t conc.	15 – 20 L oil/t conc.

Slag Cleaning. In practice two methods are used: froth flotation and treatment in small electric slag furnaces. The decision for one or the other is determined by economics. In froth flotation the slag concentrate is returned to the feed, and the tailings are discarded. The second method involves the reduction of flash furnace slags in an electric furnace, which yields a matte and slag that is suitable for sale.

Off-gas and Flue Dust. The waste gases are separated from part of the flue dust at ca. 1300 °C in the off-take shaft and pass through a waste-heat boiler for generating steam, and subsequently to an electrostatic (Cottrell) precipitator for separating the mass of flue dust, which is recycled to the feed. The precleaned off-gas with SO_2 content of >20 % is usually processed to sulfuric acid.

The flue dust consists chiefly of sulfates and basic sulfates of copper, lead, and zinc, as well as some volatile compounds of arsenic, antimony, bismuth, and selenium. Repeated recycling makes it possible to enrich selected elements for later extraction. The quantity of flue dust is between 4 and 10 % of the input.

Process Control. Five main parameters have to be controlled and adjusted carefully to obtain the highest smelting rate of concentrate, constant matte composition, specified slag composition and furnace temperatures, and minimum energy consumption:

1) Concentrate feed rate
2) Flux and recycled materials feed rate
3) Blast input and temperature
4) Oxygen enrichment of the blast
5) Fossil fuel combustion

In the flash smelters constructed between 1980 and 1999 most of these parameters are measured and adjusted automatically.

Special Operations. There are several variations on the Outokumpu flash smelting process.

Two Outokumpu copper smelters (Tamano, Japan and Pasar, Philippines) have inserted carbon electrodes in the settler. The electrodes are submerged in the slag layer to heat the slag with electric power. The system was installed to recover Cu from the slag and reduce magnetite without using an additional slag-cleaning furnace [80], [226]. The system at Tamano Smelter ceased operation in 1988 because the operators found that combustion of coke – oil mixtures also gives low copper content in the slag (0.6 %) [227].

Occasionally molten converter slag is recycled through the flash furnace like in a reverb. It is added from ladles through a spoon and launder system high on the flash furnace [228].

At two smelters in the world Outokumpu flash furnaces are used to smelt blister directly from concentrate (see Section 5.8).

Trends. The diversity of modified furnace constructions and operating methods shows the adaptability of the Outokumpu process to different raw materials and smelter locations. As increasing oxygen content has been used in the blast air, the process has approached the principle of INCO flash smelting. On the other hand, newer developments aim at the production of blister copper or white metal (75 – 80 wt % Cu) from concentrates in only one vessel, thereby approaching continuous smelting and converting as in the Noranda process.

5.5.2. Inco Flash Smelting

Inco Metal Co. was the first company in the nonferrous metal industry to use commercially pure oxygen for autogenous flash smelting. After tests in the late 1940s, two smaller furnaces went into operation in 1953 [82]. Today a total of five Inco furnaces are operating worldwide (including Ni/Cu and one older plant in Uzbekistan [83]). Since 1990 no Inco furnace has been built.

Figure 17. Inco flash smelting furnace

Furnace Design. In contrast to Outokumpu-type furnaces the Inco process uses pure commercial oxygen (95 – 98 %) instead of enriched air. The oxygen blast and concentrate are fed through the burners (generally two) in the side walls of the furnace. The furnace is smaller than the Outokumpu furnace and has only one shaft, which is located at the center of the roof and takes the off-gas to the cooling system. Using pure oxygen makes the off-gas volume much smaller than in the Outokumpu furnace. Figure 17 shows a sectional view of an Inco flash furnace. The burner is completely different from the Outokumpu type. It has low velocity of about 30 m/s into the furnace. This gives a short flame and also low flue dust generation. The Inco furnace is not equipped with other fossil-fuel burners. Because of the small size of the furnace and

the surrounding equipment, this process is suitable for replacing old furnaces within existing smelters.

Operation. Dry concentrate and flux are fed continuously to the Inco furnace. The products of the process are matte (50 – 60 % Cu), slag, and off-gas with 70 – 80 % SO_2. The slag is tapped at the sidewalls of the furnace, and the matte in the middle part under the offtake. The temperatures are similar to those of the Outokumpu furnace. In contrast to an Outokumpu furnace the amount of energy which is removed with the off-gas is much lower because of the small off-gas quantity. Therefore the Inco furnace is not equipped with a waste-heat boiler for energy recovery. The off-gas is cooled by different techniques such as splash towers, cyclones, or scrubbers [229]. The absence of a waste-heat boiler avoids out-of-service times of the furnace. Furthermore, the copper content in the slag of the Inco furnace is lower (0.5 – 1.5 %), and a slag-cleaning furnace is not needed. Only Hayden Smelter operates an additional electric furnace. Some operating data of the Chino, New Mexico furnace are listed in the following:

Furnace commissioning date	1984
Size, inside brick, m hearth $w \times l \times h$	$5.6 \times 23 \times 5$
gas-off take $w \times h$	3.9×7.7
Concentrate throughput, t/d	1520
Blast temperature, °C	40
Oxygen enrichment, %	98
Blast flow-rate, m^3/h (STP)	12 500
Matte grade, % Cu	58
Off-gas volume, m^3/h (STP)	20 000
SO_2 Content	75
Recycling of converter slag	in flash furnace
Slag treatment	discarded
Fossil fuel input	0

Process Control. The aim of running the Inco furnace is the same than the Outokumpu furnace: highest throughput rates with constant furnace properties such as matte concentration and furnace temperatures. In comparison with the Outokumpu process, it is more complicated to keep the matte grade constant because the oxygen enrichment is not adjustable. This could be done by adjusting the mix of the feed (high or low in copper) or adding fossil fuel for oxygen consumption. But this is in conflict with the principle of the process and does not seem economic.

5.5.3. KIVCET Cyclone Smelting

Developments in power-plant technology have led to adoption of the cyclone principle by the metallurgical industry. The acronym KIVCET uses the initial letters of the following Russian terms: oxygen, vortex, cyclone, electrothermic. The development began in 1963, and the first plant was operated by Irtysh Polymetal Combine in Glubokoe, Kazakhstan. The process is not widely used for copper smelting.

The method is aimed at processing copper sulfide concentrates that contain considerable amounts of other metals. The essential part of the continuously operated plant is the smelting cyclone, in which the concentrates are fed vertically, and technical-grade oxygen ($\leqq$95 %) is blown in horizontally, so that reaction takes place rapidly above 1500 °C.

The furnace is divided to allow separating and settling of the reaction products, in this respect similar to a reverb. In contrast to the separation chamber, the atmosphere in the electrically heated settler is maintained in a reducing state so that the slag does not need special posttreatment.

The off-gas volume is small, and the content of SO_2 can be up to ca. 80 %. Metals are recovered from the flue dust of both the separating chamber and the settler. Table 13 and Figure 18 explain the process.

Table 13. KIVCET process: analysis and yield [84]

Analysis and yield	Metal		
	Cu, wt %	Zn, wt %	Pb, wt %
Analysis			
Concentrate *	25.6	10.0	1.7
Copper matte	50.0	2.5	2.0
Slag	0.35	3.5	0.2
Yield			
In matte	99.1	12.7	60.0
In oxidic condensate	–	71.0	34.1

* Also 24.0 % Fe and 33.0 % S.

5.5.4. Contop Matte Smelting

Using a KIVCET license, KHD Humboldt Wedag AG, Cologne developed the combined Contop process [85]. Contop stands for continuous smelting and top blowing. It is a combination

Figure 18. KIVCET furnace [84]
a) Smelting cyclone; b) Separating chamber; c) Cyclone waste-gas offtake; d) Partition wall; e) Settling reduction hearth; f) Slag tap hole; g) Feed of reductant and offtake for waste gas from the hearth; h) Electrical resistance heating; i) Matte taphole

of a high-intensity smelting process in a cyclone and secondary treatment of the molten phase with a top-blown jet. Contop-type cyclone burners have been used on reverberatory furnaces, for example, at Chuquicamata and Palabora. In 1993 a complete Contop smelter started operation at El Paso (Asarco) [230], replacing the old reverberatory furnace. The furnace is shown in Figure 19. It is a kind of a hearth furnace. Two cyclone burners are placed on the top of one end of the furnace. Each is fed with about 25 t/h of dry concentrate and flux and about 95 % oxygen blast. Natural gas is fed to the cyclone for energy adjustment. The cyclones are made of stainless steel and are water-cooled and about 2 m in diameter and 4 m in height. Inside they are protected by a layer of solidified matte – slag. Matte with 55 – 60 % Cu is produced. At the other side of the furnace the off-gas is passed through a waste-heat boiler. The amount of off-gas is about 65 000 m^3/h (STP) with about 24 % SO_2. Its temperature is about 1150 °C. After cooling, the gas is washed and sent to sulfuric acid production.

To keep the slag hot, oxy-fuel burners are installed on the roof of the furnace between the cyclones and the off-gas shaft [231]. The slag contains 0.8 % Cu and can be discarded. The advantage of the Contop cyclone is high flexibility in concentrate composition, low dust production (ca. 2 % of the feed material), high volatilization of zinc and bismuth from dirty concentrates, and potential steam generation from the cyclones. Compared with Outokumpu flash smelting, the Contop process is more energy intensive (higher specific cost per tonne of concentrate). Another disadvantage is the relatively short lifetime of the cyclone (about one year). Therefore only one plant was built until now.

Figure 19. Contop furnace

5.5.5. Flame Cyclone Smelting

The flame cyclone reactor (FCR) process was suggested by LURGI and Deutsche Babcock AG ca. 1975 and has been demonstrated at a pilot plant of Norddeutsche Affinerie in Hamburg with a capacity of ca. 10 t/h. It is a high-temperature (> 1500 °C) reaction for autogenous smelting of copper sulfide concentrates in a high-oxygen atmosphere (up to ca. 75 %). A second characteristic is the simultaneous removal

of volatile compounds of other elements, such as zinc, cadmium, tin, lead, arsenic, antimony, and bismuth, as oxides and basic salts, in the flue dust. The SO_2 content of the off-gas is greater than 50 %. The products are a high-grade matte, containing up to 80 % Cu, and slag, which separates in a settler [86].

The principle of this method differs from that of the KIVCET process in that the reaction in the FCR process takes place in a special chamber situated before the cyclone, where the molten droplets are separated by centrifugal force. The process is well suited for processing complex or dirty concentrates, but until now never installed in practice.

5.6. Discontinuous Matte Conversion

Matte produced by smelting processes is treated in the molten state by blowing with air; this stage of concentration is known as converting. Copper and iron sulfides, the main constituents of matte, are oxidized to a crude copper, ferrous silicate slag, and sulfur dioxide.

The batch converting process has been employed for many decades in two operating steps at ca. 1200 °C in the same vessel. Investigations and development of continuous methods are being made [87], [88].

The conventional converting of matte is a batch process that yields in the first step an impure copper(I) sulfide containing ca. 75 – 80 wt % Cu, the so-called *white metal*, and in the second step the converter, or blister, copper averaging 98 – 99 wt % Cu. The name *blister copper* derives from the SO_2-containing blisters that are enclosed in the solidified metal.

First Step. The main reactions are oxidation of iron(II) sulfide and slagging of iron(II) oxide by added silica [*7631-86-9*] flux:

$$2\,FeS + 3\,O_2 \longrightarrow 2\,FeO + 2\,SO_2$$

$$2\,FeO + SiO_2 \longrightarrow Fe_2SiO_4$$

Formation of magnetite occurs near the tuyeres:

$$3\,FeS + 5\,O_2 \longrightarrow Fe_3O_4 + 3\,SO_2$$

Copper(I) sulfide is partially oxidized, but it is also reformed

$$Cu_2S + 1.5\,O_2 \longrightarrow Cu_2O + SO_2$$

$$Cu_2O + FeS \longrightarrow Cu_2S + FeO$$

In Figure 6, the first step corresponds to moving along the pseudobinary Cu_2S – FeS line to form an impure copper(I) sulfide.

Second Step. Continuing oxidation occurs as in a typical roasting reaction process:

$$\begin{array}{l} 2\,Cu_2S + 3\,O_2 \longrightarrow 2\,Cu_2O + 2\,SO_2 \\ 2\,Cu_2O + Cu_2S \longrightarrow 6\,Cu + SO_2 \\ \hline Cu_2S + O_2 \longrightarrow 2\,Cu + SO_2 \end{array}$$

In Figure 6 and Figure 20, the composition moves along the Cu_2S – Cu line from the copper(I) sulfide to crude metallic copper, the two phases being immiscible.

Figure 20. The Cu – Cu_2S system [89]

The blister copper contains < 0.1 wt % S, ca. 0.5 wt % O, and traces of other impurities.

Converter Slags. The slags from the first step are iron(II) silicates (40 – 50 wt % Fe) with high magnetite content (15 – 30 wt % Fe_3O_4). The initial copper content of 3 – 8 wt % can increase up to 15 wt % at the end of the reaction by formation of copper(I) oxide. This slag can

be decopperized by returning it to the smelting unit or by froth flotation (cf.page 28).

The high-viscosity small-volume converter slags from the second step have a high copper content (20 – 40 wt %) in the form of copper(I) oxide or silicate. When enough slag has accumulated, it is returned to the first converting stage.

Temperature. Converting is a strongly exothermic process that can overheat during oxidation of iron-rich mattes. The temperature must be held ca. 1200 °C by adding fluxes, copper scrap, precipitates from hydrometallurgical treatment (e.g., cement copper), or concentrates. The off-gas (5 – 10 vol % SO_2) is transferred to a sulfuric acid plant.

The blowing time per batch is a few hours; however, as the copper content of the matte increases, the converting time decreases. Occasionally, oxygen-enriched air is used to increase the throughput.

Impurities. The distribution of other elements among the phases during converting is as follows:

1) Noble metals and most of the nickel, cobalt, selenium, and tellurium collect in white metal and then in blister copper.
2) The bulk of zinc and some nickel and cobalt collect in converter slag.
3) The oxides and sulfates of arsenic, antimony, bismuth, tin, and the basic sulfates of lead are found in flue dust.

Converter Types. The copper converter was invented in 1880 by Manhès and David, based on the Bessemer converter, which had been used in the steel industry since 1855. This development led to the incorrect name "copper bessemerizing," although the true Bessemer process is a refining step. Originally, the copper converter was upright, and such obsolete units were in operation until the early 1980s, e.g., the Great Falls converter developed by Anaconda Mining Co., United States.

The following types are in use currently (Fig. 21):

1) The Peirce – Smith converter has been the most important apparatus for converting for many decades, and the number in operation may be in the range of a thousand. More than 80 % of the worldwide produced copper comes from this type of converter. It is a horizontal cylinder lined with basic bricks (magnesite, chrome – magnesite) that can be rotated about its long axis (Fig. 22); blast air is blown through a horizontal row of tuyeres. In practice, the punching of tuyeres with special devices is necessary to maintain the flow of air. The largest vessels are 12.5 m long with a diameter of 4.6 m.
2) Hoboken or syphon converter [91]. This variation of the P – S type was developed years ago by Metallurgie Hoboken N.V., Belgium, but is now used by only a few smelters in Europe and in North and South America; larger units are operated at Glogow smelter in Silesia, Poland; Cyprus Miami Smelter in Arizona; and Paipote smelter (ENAMI), Chile [92]. Its advantage is its freedom from sucking in air, so the off-gas can attain SO_2 levels up to 12 %. Special features of the design are the small converter mouth and the syphon or goose neck that guides the off-gas and flue dust flow.
3) Inspiration converter [93]. The vessel has two mouths, the smaller for charging, the larger for the off-gas. The latter is well hooded in all operating positions. It is only in operation at Cyprus Miami Smelter.
4) Top-blown rotary converter [95]. The TBRC, which is known in the steel industry as the Kaldo converter, was adopted by the nonferrous industry (first by INCO, Canada) because of its great flexibility. Air, oxygen-enriched air, or on occasion, commercial oxygen is blown through a suspended water-cooled lance onto the surface of a charge of copper-containing materials. In practice, the TBRC is used batchwise for special operations on a small scale, but generally not for converting copper matte. Tests of direct smelting of concentrates (clean, complex, or dirty) to white metal or blister copper were performed at Rönnskär smelter (Boliden Metall AB), Sweden, but the process was not realized technically. Copper extraction from copper scrap and other secondary materials is also carried out. The TBRC is also well suited for lead/precious metals metallurgy.

Figure 21. The evolution of the copper converter [90]

Figure 22. Schematic cross section and back view of a Peirce – Smith converter [96]

Developments for Increased Productivity and Environmental Protection To increase the productivity of a Peirce – Smith converter, usually the oxygen enrichment in the blast is increased. Depending on process step (slag or copper blowing) up to 30 % O_2 is used. The resulting increases in the temperature in the vessel must be controlled. Copper smelters mostly in Europe or Japan add copper scrap during the copper blow phase to adjust the temperature in the converter bath. Special systems (lift and conveyor) have been developed to add up to 70 % of the cooling material without stopping blowing [232], [233] (Figure 23).

Figure 23. Machine for automatic charging of cooling material

Automatic temperature measurement (optical spectrometer or thermocouple through the tuyere) is used for process control and to avoid high erosion of the brick lining of the converter. Also the chemistry of the converting process is monitored by optical spectrometry [234]. This allows the blowing time to be easily controlled without overblowing the charge and thus minimizes the copper loss to the converter slag and magnetite formation in the slag. High-velocity tuyeres have been developed [235], [236] which can be operated with high oxygen enrichment without extensive refractory erosion. At the front of the tuyere a tubular accretion is formed which protects the brick lining. Another advantage is that these tuyeres need not be punched (saves labor and maintenance cost). A disadvantage is the relatively high pressure of about 3 bar of compressed air (high investment). These high-velocity tuyeres have been tested in Peirce – Smith and Hoboken converters. Today (ca. 2000) the first smelters (Hidalgo) are planing to install the system.

One of the problems of Peirce – Smith converters is leakage SO_2-containing off-gas during charging and pouring operations in the working environment. To avoid these fugitive emissions, special secondary hooding systems have been developed and installed. For example, Figure 24 shows the hooding system used at Norddeutsche Affinerie. The collected fugitive gases are dilute in SO_2 (up to 0.2 %) and are treated by various techniques (scrubbing with basic solutions or dry absorption of the SO_2 producing gypsum) [237], [238].

5.7. Continuous Matte Conversion

While continuous copper matte smelting processes have been in operation for many years, continuous converting of matte has come into use slowly. The potential benefits are minimization of materials handling (especially overhead crane transport of liquids), more efficient off-gas capture, and continuous SO_2 production for the sulfuric acid plant. Two multiple-furnace processes are used today for continuous smelting and converting: the Mitsubishi process and the Kennecott/Outokumpu Flash converting process. Noranda has developed a continuously running converter which has been in operation since 1997 at Horne Smelter.

5.7.1. Noranda Process

In the 1970s Noranda started with the Noranda reactor for directly smelting blister. This was not useful and was therefore switched to smelting high-grade matte. A second reactor similar to the smelting one is proposed for continuous conversion of matte (patented 1985 [239]). Since 1997 it has been operated at Horne smelter. It is a horizontal cylindrical vessel with two mouths (one for adding liquid matte by ladle, the other for the off-gas) and a row of submerged tuyeres. There is also the possibility to feed solid matte or coal by slinger belt through one end wall. The converter is usually fed with liquid high-grade matte (70 % Cu) from the Noranda smelting reactor. It produces semi-blister copper with high sulfur content (1 – 1.5 %). The semi-blister is poured into a ladle which is transported by special ladle car to the anode furnace. The Noranda converter can be operated in four

Figure 24. Hooding system for the prevention of fugitive emissions at Norddeutsche Affinerie

modes: with molten matte feed, with any combination of solid and molten matte feed, up to 100 % solid feed, in smelting mode with concentrate like the Noranda reactor and a conventional Peirce – Smith converter. The converter at Horne Smelter (Figure 25) [240] is 4.5 m in diameter and 19.8 m long (inside the brick lining). It has 42 tuyeres. The process off-gas is collected in a water-cooled hood and sent to the sulfuric acid plant. The converter has a secondary ventilation system, the gases of which are sent directly to a stack. This process operates continuously and has very high flexibility but not all of the potential benefits have been achieved. There is still crane transport and handling with ladles which causes fugitive emissions.

5.7.2. Mitsubishi Process

Mitsubishi Metals Corp., Japan, tested the new concept during the 1960s and started the first commercial plant at Naoshima smelter in 1974. Today (ca. 2000) four companies are operating this process (Naoshima, Japan; Kidd Creek, Canada; LG Metals, Korea; Gresik, Indonesia). The principle of this process is the interconnection of three furnaces, as shown in Figure 26 [241], [242]:

1) Smelting or S-furnace: Dried concentrates, flux material, pulverized coal, return converter slag, copper scrap, and flue dust are smelted in this furnace. The fine material (concentrate, coal) is fed through nine or ten vertical steel lances on the top of the molten bath. The blowing lances consist of two concentric pipes. Through the inner pipe, the dried concentrate is air blown, and through the outer one, oxygen-enriched blast (40 – 50 % O_2). The lances are rotated to prevent them sticking in the roof. They extend to 0.5 – 1 m above the molten bath. About 0.3 – 0.5 m of the lance is consumed each day. The off-gas contains 30 – 45 % SO_2 and is sent to sulfuric acid production.
2) Slag-cleaning furnace: Slag and matte from the S-furnace flow continuously by gravity into the elliptical slag-cleaning furnace, which is an electric furnace with three or six submerged graphite electrodes. The temperature of the slag is kept at 1250 °C. The slag is decopperized to 0.6 – 0.9 % Cu and discarded. The matte flows continuously through a siphon into the converting furnace.
3) Converting or C-furnace: The matte (68 % Cu) is converted continuously by blowing enriched air (30 – 35 % O_2) and $CaCO_3$ flux through six lances on the top of the bath. Also copper scrap is added through the sidewall of the furnace. Conversion only takes place where the oxygen comes into contact with the

Figure 25. Noranda converter at Horne Smelter

sulfides. This is achieved by running the converter with a special basic calcium ferrite slag (40 – 50 % Fe, 15 – 20 % CaO). The usual silica slag is not possible because when oxygen is blown onto the top, solid magnetite is formed and blocks the surface. In the calcium ferrite slag dissolves the magnetite but also a large amount of copper (15 – 18 %). The converter slag is returned to the S-furnace. The blister copper contains slightly more sulfur (0.7 %) than from a Peirce – Smith converter (0.02 %). It is sent to an anode furnace.

Some operating data for the Mitsubishi process (Naoshima Smelter, Japan) are summarized in the following:

Commisioning date	1991
S-furnace	
Diameter inside brick, m	10
Number of lances	9
Concentrate throughput, t/d	2050
Copper scrap, t/d	20
Blast, m^3/h (STP)	37 500
O_2 enrichment, %	49
Off-gas volume, m^3/h (STP)	39 000
SO_2 in off-gas, %	29
Matte grade, %	68
Slag-cleaning furnace	
Size, inside brick $w \times l \times h$, m	$6 \times 12.5 \times 2$
Number of electrodes	6
Residence time	ca. 2 h
Slag	0.6 % Cu
Off-gas volume, m^3/h (STP)	50
C-furnace	
Diameter inside brick, m	8
Number of lances	10
oxygen enrichment, %	33
Blast flow rate, m^3/h (STP)	25 500
Copper Scrap, t/d	190
Off-gas volume, m^3/h (STP)	25 000
SO_2 in off-gas, %	26

The major advantage of the Mitsubishi process are the good SO_2 capture and the lower handling expense of materials. A disadvantage during the initial operating time was that no scrap material could be added. This is has now been solved [243]. With a smelting capacity of about 2000 t/d of copper concentrate, Naoshima Smelter processes also about 40 000 t/a of copper scrap from the market and additional anode scrap from the refinery. Another problem is the impurity behavior. Especially lead is a problem because of the calcium ferrite slag. If too much lead is in the feed, the copper anodes are too rich in lead for electrorefining. A comparison of the impurity behavior is given in Table 14.

Table 14. Impurity contributions to anodes (wt % of input)

Process	Reverbatory/Peirce – Smith	Mitsubishi
Pb	8 – 13	15 – 19
As	9 – 11	4 – 6
Sb	28 – 34	15 – 20
Bi	14 – 26	15 – 25
Ni	45 – 50	67 – 75

Figure 26. Mitsubishi process

5.7.3. Kennecott/Outokumpu Flash Converting Process

In the 1980s Kennecott announced the development of their Solid Matte Converting (SMOC) process [244]. This process is based on solidifying the molten matte from the smelter, grinding, and feeding the solid to an high-oxygen blast converter. This process decouples the smelting and converting steps and gives great flexibility. Later on, it was developed with Outokumpu, and for the converting step also a well-proven flash furnace was chosen. In 1995 the process went into operation at Garfield Smelter.

For matte smelting a flash furnace with a concentrate feed rate of about 140 t/h was built (oxygen enrichment 65 – 75 %). The liquid matte contains 68 – 70 % copper and is granulated in water. In the second step the matte is milled and then fed together with lime as flux material to the flash converter, which operates with an oxygen enrichment of 65 – 75 % O_2. The feed rate of matte is about 60 t/h (up to max. 80 t/h) [245]. This furnace is constructed like the smelting furnace. A blister copper and a calcium ferrite slag with about 18 % copper (like in the Mitsubishi process) is obtained. The slag is granulated and fed back to the flash smelter.

The off-gases contain >30 % SO_2 and are converted to sulfuric acid (input concentration of 14 % SO_2 in the sulfuric acid plant). This process has very low SO_2 emissions of only 3.5 kg SO_2 per tonne of copper, which is until now the lowest in the world. This is achieved because it has almost no fugitive emissions. The disadvantage is that no scrap can be added to the converter.

5.8. Direct Blister Smelting

Normally copper extraction takes place in two steps – concentrate smelting and matte converting – in which the chemical reactions are principally the same: oxidation of Fe and S. It has long been the aim to combine these processes in a single step/reactor and minimize the energy consumption and operating cost. Today (ca. 2000) direct blister smelting is carried out at two smelters (Glogow, Poland and Olympic Dam, Australia) in a Outokumpu flash furnace. Between 1973 and 1975, Noranda also used their reactor for blister smelting from concentrate, but it was switched to matte smelting because of impurity problems. Another proposal is the QS process.

5.8.1. Blister Flash Smelting [246]

This process takes place in a conventional Outokumpu flash smelting furnace. Concentrate and silica flux are fed with 60 – 85 % O_2 blast to the burner. The amount of O_2 is just enough to form blister copper. In practise, the particles in the reaction shaft are somewhat over-oxidized on the outside and incompletely oxidized on the inside. In the molten bath layers the reaction is

completed to form blister copper and iron silica slag. Formation of a layer of matte between blister and slag must be avoided, because otherwise a pronounced foaming reaction could take place.

In both operations copper concentrates with low iron content (e.g., chalcocite, bornite) are processed to minimize slag production and copper loss in the slag. The slag has a high copper content (15 – 21 % Cu), mainly in oxidized form, and has to be reduced in an electric furnace (produces copper – iron – lead alloy [247]) or concentrated by grinding and flotation. Reduction in an electric furnace with addition of coke takes about 12 h residence time. The furnace is operated at higher temperatures than the normal flash smelter (slag temperature 1300 °C) to obtain higher solubility of magnetite in the slag and decrease the viscosity of the slag. The blister copper contains 0.3 – 1 % S. At the Glogow Smelter, the process has been in operation since 1977 with a daily throughput of 1500 t of concentrate. At Olympic Dam it has been operated since 1988 and was enlarged in 1998.

5.8.2. QS Process

The QS process, based on the QSL leadmaking process, was invented by Queneau and Schuhmann in 1974 [109]. Blister copper is produced from concentrate in a single vessel. The reactor is similar to the Noranda reactor but has countercurrent flow of slag and matte. Gases are injected from the bottom [248] of the vessel to oxidize Fe and S and to reduce the copper content in the slag (Figure 27). Although the process has fundamental and technical merits, it has not been realized in a commercial plant.

5.9. Copper Recycling

Most copper (> 95 %) is used in metallic form, as copper metal or copper alloys. Recycling of copper and its alloys has been carried out since ancient times. In 1997, 37 % of copper consumption came from recycled copper. This low figure could be explained by the long lifetime of copper products (e.g., more than 30 years for copper wire) and the much increased copper production in the last 50 years. Virtually all products made from copper can be recycled, and copper can be recycled over and over again without losing its chemical or physical properties.

The processes used for copper recycling depend on the copper content of the secondary raw material, its size distribution, and other constituents (Table 15) [249], [250]. Three general types can be defined:

Type 1: copper scrap (new and old scrap), used for smelting and refining or direct smelting for products. This type accounts for about 95 % of all recycled copper. The value of the metal is much higher than its treatment costs.

Type 2: copper-containing special scrap such as cables and printed circuit boards. Pretreatment (e.g., cable comminution) is necessary before smelting the copper. Another example is copper in cars. Each car contains 10 – 30 kg of Cu which must be separated from the iron. The value of the material is in the range of the overall treatment cost.

Type 3: copper-containing residues, for example sludges from metal-plating industry. The copper content of these materials is low. The value of the copper is much lower than the treatment cost of the material.

High-purity secondary copper material is used for smelting and casting new products, and no fire and/or electrolytic refining is necessary. This is also true of pure alloy scrap, which is used for fresh alloy. With increasing impurity content, the material is fed to smelting and refining processes. The process steps and aggregates of secondary smelters are generally similar to those of primary production, but the secondary raw material is usually metallic or oxidic [253]. Therefore, mainly reducing conditions are used for secondary smelting. Often carbon in the form of coke or natural gas is used.

For smelting metallic scrap, often shaft furnaces (Asarco type or Contimelt) are used. For smelting oxidic materials, blast furnaces, electric furnaces, TBRCs, and Isasmelt furnaces are used. In the TBRC both the smelting and the converting step could be done. This saves energy in comparison with the blast furnace and Peirce – Smith converter. In some cases electric arc furnaces are used instead of the blast furnace. The advantage is that this furnace produces about 80 % less off-gas than the blast furnace. This makes the capture easier and more efficient.

Figure 27. QS process

Table 15. Overview of different sorts of secondary copper sources

Type	Material	Cu content, %	Source	Recycling process
1	mixed copper scrap	90 – 95	sheets, gutters, water boilers, heaters, wires, pipes	converting, fire refining
1	pure copper scrap	99	semi-finished products, wire, strip, cuttings	melting and casting of semifinished products
1	red brass scrap	75 – 85	valves, taps, machine components, fittings, bearing boxes, car radiators	converting or alloy production
2	shredder material	60 – 65	cars	blast furnace, electric furnace, TBRC
2	cable	40 – 50	buildings, cars	shredder, firerefining
2	electronic scrap	10 – 20	electronics	converting, TBRC
3	sludges	5 – 10	electroplating	blast furnace, Electric furnace
3	copper – iron material	10 – 20	armatures, stators, rotors	blast furnace, electric furnace, TBRC
3	drosses, ashes, slags	20 – 25	foundries	blast furnace, electric furnace, TBRC

A typical flow sheet of a secondary smelter is shown in Figure 28.

Many primary smelters treat scrap besides their internal recycling materials like anode scrap from the tankhouse or converter flue dusts. Additional copper scrap bundles are fed to the Peirce – Smith matte converter. The scrap cools the converters and uses the energy from matte oxidation for heating and melting.

Also electronic scrap such as printed circuit boards is fed to copper matte converters (e.g., Norddeutsche Affinerie [251], [252]) or Noranda reactors (e.g., Noranda). The copper and the precious metals are captured and sent to subsequent refining. The organic polymers are burnt at the high temperatures, and water and CO_2 are formed; ceramics are slagged. Because of the high temperature and the high SO_2 content in the off-gas, no dioxins are formed.

5.10. Hydrometallurgical Extraction

About 15 % of the primary copper production in the western world, that is, about 1.8×10^6 t/a, results from sulfuric acid leaching of copper ore, which is combined with solvent extraction and electrowinning. Other proposed techniques like ammonia leaching or hydrochloric acid leaching have minor importance. They are mainly proposed for treating concentrates. A typical flow sheet of a sulfuric acid leaching operation is shown in Figure 29.

Chemistry Of Sulfuric Acid Leaching Processes. There are two chemically different classes of copper minerals:

1) Oxidic or secondary minerals like malachite and chrysocolla
2) Sulfidic or primary minerals like chalcopyrite and chalcocite

The sulfidic minerals are the most common in an ore body. Oxidic minerals are often located on the top of the ore body and are present in smaller amounts.

Chemical reactions during extraction of copper from primary and secondary minerals are as follows:

Figure 28. Flow sheet of a secondary smelter

Figure 29. Sulfuric acid leaching of copper ores

Oxidic secondary copper minerals:

$$CuCO_3 \cdot Cu(OH)_2 + 2\,H_2SO_4 \longrightarrow 2\,CuSO_4 + 3\,H_2O + CO_2$$

Sulfidic primary copper minerals:

First step: generation of Fe^{3+}, which is the oxidant for copper leaching, by bacteria.

Thiobacillus thiooxidans:

$$2\,FeS_2 + 7\,O_2 + 2\,H_2O \longrightarrow 2\,FeSO_4 + 2\,H_2SO_4$$

Thiobacillus ferrooxidans:

$$2\,FeSO_4 + 0.5\,O_2 + H_2SO_4 \longrightarrow 2\,Fe^{3+} + 3\,SO_4^{2-} + H_2O$$

Second step: attacking the chalcopyrite:

$$2\,Fe_2(SO_4)_3 + CuFeS_2 + 3\,O_2 + H_2O \longrightarrow 5\,FeSO_4 + CuSO_4 + 2\,H_2SO_4$$

Secondary minerals are readily soluble in sulfuric acid, and reaction times are typically short. After several hours most of the copper is extracted, but sometimes the ore requires a few weeks reaction time. Recovery of copper from primary minerals is more difficult because the sulfides are very stable, and apart from sulfuric acid an oxidant is required as well. The most important oxidant is Fe^{3+}, which is generated from the mineral chalcopyrite by bacteria-assisted reactions with atmospheric oxygen. Although these bacteria, which normally exist in the mine water, speed up the process, very long reaction times like months or years are still necessary to extract most of the copper. The consumption of sulfuric acid depends on the type of copper mineral. The bacterial leaching process produces sulfuric acid itself.

Industrial Leaching Processes. The copper leaching techniques in practical use are listed in Table 16.

The most important technique is heap leaching. It is very common for oxidic copper ore. The typical copper content is between 0.25 and 1 %. The ore is crushed to 1 – 10 cm and stacked to heaps 3 – 10 m high with an area of about 10 000 to 100 000 m^2. Dilute sulfuric acid is sprayed on the top of the heap. The liquor trickles through the material, copper is dissolved, and the copper-bearing solution (1 – 5 g/L Cu) is collected at the bottom of the heap. This copper solution is purified and enriched by solvent extraction. Copper metal is generated by electrolysis of the enriched solution. After several months (1 – 6), leaching is stopped and a new heap is placed on the top of the previous and leaching is begun again.

Data from a typical heap leaching plant are shown in Table 17. To produce 54 000 t/a of copper, 27 000 t ore per day must be treated.

Table 17. Typical data of heap and dump leaching operation

	Heap leaching	Dump leaching
Cu cathode production, t/a	54 000	6600
Leach ore composition	chrysocolla	95 % chalcopyrite, 3 % chalcocite
Soluble Cu in ore, %	0.54	0.15
Total area under leach, m^2	200 000	300 000
Tonnes of ore per day	27 000	55 000
Annual Cu recovery rate, %	90	20
Sulfuric acid consumption, t/t Cu	1.7	0

The copper production of a typical dump-leaching operation is much lower, for example. 6600 t/a. The feed material is very low grade sulfidic ore, and several years are required to extract all the copper. The sulfuric acid consumption depends on the mineralization of the copper ore and the composition of the host rock. Typical figures are in the range of 1 – 5 t of sulfuric acid per tonne of copper product.

Minor methods are in situ leaching, tailings leaching, and vat leaching. Vat leaching was carried out in the past to produce a pregnant leach solution with about 30 g/L Cu which was directly suitable for electrowinning. This technique is replaced by heap leaching and SX. Agitation leaching is used mainly to leach oxidic Cu concentrates in Zaire and Zambia. Fine particles are treated with strong sulfuric acid (ca. 60 g/L) solution, and the reaction is complete after several hours.

Other Leaching Processes. Mainly for the leaching of sulfidic copper concentrates, many processes have been developed.

The *Arbiter/Escondida Process* was developed for leaching mainly chalcocite concentrates. In ammonia solution, half of the copper is extracted very quickly and CuS remains in the residue.

$$Cu_2S + 2\,NH_3 + 2\,NH_4^+ + 0.5\,O_2 \longrightarrow CuS + [Cu(NH_3)_4]^{2+} + H_2O$$

Table 16. Common techniques for sulfuric acid leaching of copper mine

Leaching technique	Mineralization	% Cu in ore	Leaching time	Estimated Cu production (1998), T/A
Heap	oxides, chalcocite	0.25 – 1	several months to years	700 000
Dump	chalcopyrite	< 0.25	1 – 5 decades	50 000
In Situ	all	> 0.5	decades	50 000
Vat	oxides	1 – 2	5 – 10 d	50 000
Agitation	oxides (carbonates)	20 – 40	2 – 5 h	200 000
Tailings	oxides (carbonates)	0.25 – 1	1 d	100 000

The reaction takes place in agitated vessels. The copper complex solution is sent to a solvent extraction and electrowinning plant. The residue is sent to a flotation plant, where copper is enriched, and then fed to a smelter. This process was operated at Escondida mine in Chile but at present is shut down.

The *Cuprex process* uses iron(III) chloride for the oxidation of copper from chalcopyrite:

$$CuFeS_2 + 4\,FeCl_3 \longrightarrow CuCl_2 + 5\,FeCl_2 + 2\,S$$

A solvent extraction step gives pure $CuCl_2$ solution (ca. 100 g/L Cu), which is fed to a membrane-divided electrowinning cell, where copper powder is produced and in at the anode the iron(II) chloride is oxidized to iron(III) chloride and recycled to the leaching process. The process has been tested in a 1 t/d pilot plant.

The *Intec process* is carried out in a NaCl/NaBr solution at 80 – 85 °C with $CuCl_2$ as oxidant. Leaching is carried out in four steps; gold is also leached in the last step. The residue consists of Fe(O)OH and elemental sulfur.

$$4\,CuFeS_2 + 4\,CuCl_2 + 3\,O_2 + 2\,H_2O \longrightarrow 8\,CuCl + 4\,FeOOH + 8\,S$$

The solution is cleaned by adding CaO and then sent to a membrane electrolytic cell. At the cathode copper is reduced to copper powder. At the anode two reactions take place: oxidation of Cu^+ to Cu^{2+} and oxidation of bromide ions to $BrCl^-$. This solution, which contains about 30 g/L Cu, is sent back to the leaching reactor (step 4, Au leaching).

Oxygen pressure leaching of chalcopyrite, bornite, or chalcocite concentrates in sulfuric acid under 8 bar oxygen pressure at 200 °C gives about 99 % copper recovery after a short reaction time of only one hour. The dissolved copper can be recovered by electrowinning. The leach residue can be treated with cyanide for gold recovery. This process was tested in laboratory scale. It might find use for impure concentrates or concentrates high in precious metals.

Bacterial leaching of chalcopyrite concentrates (Bio COP) is developed since 1997 at Codelco's Chuquicamata mine. The sulfide concentrate is leached in stirred tanks at 65 – 85 °C assisted by special heat-resistant bacteria (bacteria mesofila). The process needs large amounts of air/oxygen. The copper sulfate solution is fed to a SX-plant and then to copper electrowinning. A pilot plant will be built within the next 2 years.

Solvent Extraction. The pregnant leach solutions from heap, dump, or in situ leaching are too dilute in Cu (1 – 5 g/L) and too impure for direct production of high-grade copper cathodes. Industrial copper winning requires electrolytes with about 40 – 50 g/L copper. Copper enrichment and purification, mainly to remove iron, is done by solvent extraction. The dilute, impure solution from the leaching operation is mixed with an organic solution, which is based on kerosene or petroleum and contains about 5 – 10 % of an extractant which is selective for copper. The organic extractants used for the process are salicylaldoximes and ketoximes (RH) and commercially available as LIX (Henkel) or MOC (Allied Signal). The copper ions are complexed by these reagents and enter the organic phase:

$$2\,RH + CuSO_4 \longrightarrow R_2Cu + H_2SO_4$$

After mixing, the aqueous and organic phases are separated by gravity (settler). In a second step, copper is stripped from the organic phase with more highly concentrated sulfuric acid solution.

$$H_2SO_4 + R_2Cu \longrightarrow 2\,RH + CuSO_4$$

Normally, the depleted solution from electrowinning, which contains about 170 g/L H_2SO_4 and 35 g/l Cu, is used. It is enriched with copper to about 50 g/L and sent to the electrowinning cells. Depending on the composition of the dilute solution from the leaching plant several mixer/settler steps are needed for purification of the copper.

Copper Electrowinning. The copper-enriched sulfuric acid solution (ca. 40 – 50 g/L Cu, 140 – 170 g/L H_2SO_4) is sent to the electrowinning cells, which are similar in construction to refining copper cells. Copper is depleted at the cathode on stainless steel sheet (ISA Process) or copper starters. The cathode reaction is identical to the refining reaction:

$$Cu^{2+} + 2e^- \longrightarrow Cu \quad E_0 = 0.34\,V$$

The anode reaction is completely different. Inert anodes, mainly PbSnCa alloy, are used, and oxygen is formed at the anode.

$$H_2O \longrightarrow 0.5\,O_2 + 2\,H^+ + 2e^- \quad E_0 = 1.23\,V$$

The electrical potential needed for copper electrowinning is about 2 V, as opposed to about 0.3 V for copper electrorefining. About 2000 kW h is required for depleting 1 t of copper. The usual plating period is about 7 d, after which around one-third of the cathodes are taken out of the cell by crane and immediately replaced by fresh ones, in contrast to the refining tankhouse, where all cathodes are removed. The cathode replacement in the winning tankhouse is performed without cutting off the electrical power. This maintains a passivation layer on the lead anode and minimizes contamination of the copper with lead. In addition, the electrolyte contains about 100 ppm cobalt to prevent corrosion of the anodes. The lead anodes have lifetimes of up to 20 years. The current density in electrowinning plants is about 200 – 300 A/m^2. Modern electrowinning tankhouses have capacities up to 200 000 t/a of cathode copper.

Economics of Copper Production by L/SX/EW Processes Compared with copper production in smelters, L/SX/EW processes have lower production figures. But the arguments for the L/SX/EW techniques are low investment costs and increased copper output efficiency of mines. Furthermore, copper can be recovered from low-grade materials which are unsuitable for smelters. With improvements in solvent extraction and electrowinning technology, the quality of the recovered copper has become as good as that from classical refineries. Leaching facilities are mostly located at the copper mines. The disadvantage of leaching is that it does not recover the precious metals.

Production figures (in 10^3 t/a) for L/SX/EW copper by region in 1997 follow:

North America	567
Latin America	943
Oceania	49
Africa	65
Asia	4
Western Europe	2

The expected growth of western world copper production and the contributions from smelters and L/SX/EW operations is shown in Figure 30. Copper production is expected to increase from about 12×10^6 t/a in 1996 to about 14×10^6 t/a in the year 2000. The biggest part of this growth will come from L/SX/EW operations. Smelter production will also increase, but there the next step in capacity enlargement is expected after 2002.

Figure 30. World copper production statistics

Most of the increase in copper production by leaching was accounted for by Latin America (Figure 31). By 2002 or 2003, the production of L/SX/EW copper is expected to have increased by nearly a factor of three. Several new operations are scheduled for the near future.

Figure 31. Copper production by the L/SX/EW technique

6. Refining

Conventional refining comprises three stages: (1) pyrometallurgical or fire refining, (2) electrolytic refining, and (3) remelting of cathodes and casting of shapes. Refining without electrolysis is adequate if the fire-refined copper has the necessary purity and if the content of precious metals can be neglected. If extremely high-purity copper is needed, zone melting or repeated electrolysis of cathodes is used.

6.1. Pyrometallurgical Refining

Fire refining is applied to crude copper such as blister copper from converters (ca. 97–99 wt % Cu), black copper from blast furnaces (ca. 90–95 wt % Cu), cement copper from hydrometallurgical operations (ca. 85–90 wt % Cu), anode scrap from electrolytic refining, and high-grade copper scrap, chiefly unalloyed wire scrap.

The refining of molten copper to anode copper for electrolysis or commercial fire-refined copper has the following functions:

1) Removing impurities by slagging and volatilization, with the precious metals remaining entirely in the metallic copper
2) Reducing the sulfur content to ca. 0.0005–0.005 wt % by oxidation
3) Decreasing the oxygen content to $< 0.1-0.25$ % by reduction (poling) to give a flat surface as a result of the water-gas equilibrium in molten copper

6.1.1. Discontinuous Fire Refining

Two furnace types are available for batch copper refining, the older *reverberatory furnace* and the more modern *rotary furnace.* The former, which resembles smaller reverbs for matte smelting from concentrates, has a capacity of 200–400 t of copper per charge, can be fed with molten or solid copper, and is used in secondary smelters. Rotary furnaces hold up to 350 t of molten metal per charge and are generally fed only with liquid copper. This type of furnace is preferred by primary smelters because the reduction is more efficient. An extra melting furnace, e.g., anode shaft type (Section 6.1.2), can be required for remelting of solid materials (scrap and anode rests).

Low-sulfur pulverized coal, fuel oil, natural gas, or reformed natural gas serve as fuel. The refractory lining consists of basic bricks, such as magnesite or the more spall-resistant chrome–magnesite bricks.

After charging and possibly melting, oxidation and reduction stages are carried out in sequence. At the beginning of the *oxidation period,* air is blown into the melt, partly slagging and partly volatilizing the impurities. During this blowing step, a part of the copper is oxidized to copper (I) oxide, which dissolves in the liquid metal (Fig. 32). If the content of Cu_2O in copper increases to ca. 10 wt % (corresponding to $\geqq 1$ wt % O), it acts as a selective oxidizing agent:

$$Cu_2S + 2\,Cu_2O \longrightarrow 6\,Cu + SO_2$$

In practice, large amounts of SO_2 are generated so that this final stage of the oxidation period is termed boiling. Reduction of the sulfur content limits SO_2 blisters in the solid copper.

The subsequent *poling* with wood is a centuries-old method that is still employed in older reverb plants. Large tree trunks (poles) of beech, birch, eucalyptus, etc. are plunged under the surface of the melt to generate reducing gases and steam by dry distillation of the wood. The escaping gas mixture reacts with copper (I)

oxide and mixes the molten bath [1, p. 441], [2, p. 392].

This awkward operation has been largely displaced by *gas poling* [143] in rotary furnaces: natural gas (CH_4), reformed gas (CO, H_2, and N_2), propane, or ammonia [144] is blown into the copper melt through tuyeres. This process has been introduced at most smelters in the world.

Figure 32. Partial phase diagram of the $Cu-Cu_2O$ system

The poling operation proceeds in two steps. During *tight poling,* the remaining sulfur dioxide from copper (I) sulfide is almost entirely flushed out by the escaping gas, a sample of liquid copper at the end of this stage solidifying without blisters or cavities. Next comes the *poling tough pitch,* which is necessary to reduce the copper (I) oxide and achieve the required low oxygen content. High Cu_2O content in the solidified metal causes brittleness and decreased strength; moreover, Cu_2O disproportionates to copper metal and copper(II) ions in sulfuric acid electrolytes, which disturbs the electrolytic refining operation.

The final oxygen content in fire-refined *tough pitch copper* must be 0.02 – 0.05 wt %; for anodes it can be 0.05 – 0.3 wt %. The fire-refining process can be understood from the Cu – O system [145] (see Fig. 32); the system Cu – O – S is important in the oxidation period (see Fig. 5) and the Cu – H – O system for the reduction or poling period.

When a copper melt solidifies, a shrinkage of ca. 5 vol % occurs, but a flat surface can be achieved by careful control of the equilibrium

$$Cu_2O + H_2 \rightleftharpoons 2\,Cu + H_2O$$

The steam of micropores can compensate the volume difference, and a *flat set* cast is obtained.

Surface and fracture of small samples of solidified copper from the molten bath are observed during the refining process to ascertain the current state. It is also possible to measure the oxygen content of the copper melt potentiometrically.

A special problem is the extremely high copper content (up to ca. 40 wt % Cu, chiefly as Cu_2O) in refining slags. Such products are treated as high-grade oxidized copper ores.

6.1.2. Continuous Fire Refining

The two-stage Contimelt process for copper melting and refining was developed in 1968 by Norddeutsche Affinerie at Hamburg, in cooperation with Metallurgie Hoboken-Overpelt in Olen, Belgium [147]. The first stage began operation in 1979, and the complete process has been operated since 1982 on a commercial scale. The continuous operations are performed successively in two units connected by launders. First is the anode shaft furnace, where charging, melting, and oxidation of crude copper take place. Second is the small drum-type furnace, where poling and casting of anodes are carried out. The oxygen content of copper from the anode shaft furnace averages 0.6 %, with 0.15 % after poling. A feature of the shaft furnace is the additional equipment with oxygen burners for regulating the composition of the furnace atmosphere and the overheating of copper. In comparison with conventional fire refining, the Contimelt process provides savings in energy and labor.

6.1.3. Casting of Anodes

The conventional method of producing anodes is the discontinuous casting on casting wheel machines. The pure copper molds must be sprayed

with a slurry that prevents the sticking of solidified anodes; baryte, alumina, or silica flour are suitable. (Calcium-containing material is not suitable because it forms gypsum, which is partially soluble in the electrolyte.) The casting rate can reach 100 t/h. The anode weights vary between 250 and 450 kg, depending on the refinery. Anodes from modern plants usually have the following dimensions: 0.9 – 1.1 m long; 0.9 – 1.0 m wide; and 3.5 – 6.0 cm thick. They weigh 300 – 450 kg. Economic considerations call for anodes of nearly the same weight within a plant; therefore, discontinuous casting is best controlled by electronic systems.

Contilanod Process. The Contilanod process, developed by Metallurgie Hoboken-Overpelt in Olen, Belgium, produces uniform anodes by using the continuous Hazelett twin-belt casting system [148]. The continuous cast strip of anode copper formed between two belts and damblock chains is 1 m wide and 1.5 – 6 cm thick; special cutting equipment separates the strip into individual anodes 1 m long. Some refining plants use this method, e.g., White Pine, Michigan, United States; Kidd Creek, Timmins, Canada. The advantage of this system is the uniformity of the anodes and the high degree of automation. But in comparison to the mold-on-wheel technique, the Hazelett caster has somewhat higher maintenance costs.

6.2. Electrolytic Refining

About 80 % of the world copper production is refined by electrolysis. This includes all primary copper and much secondary copper. This treatment yields copper with high electrical conductivity and provides for separation of valuable impurities, especially the precious metals.

The basic patent, GB 2838, for galvanic deposition of metals was awarded to J. B. Elkington in 1865. The most important technical problems were solved by E. Wohlwill at the Norddeutsche Affinerie in Hamburg, Germany, in 1876, and this method has been used ever since. The first electrolytic copper refinery in the United States was operated from 1883 to 1918 by the Balbach Smelting and Refining Co., Newark, New Jersey.

6.2.1. Principles [149], [150]

Several possible half-reactions can occur at the electrodes.

Anode reactions	Cathode reactions	Standard electrode potential E° (25 °C), V
$Cu \longrightarrow Cu^{2+} + 2e^-$	$Cu^{2+} + 2e^- \longrightarrow Cu$	0.337
$Cu \longrightarrow Cu^{+} + e^-$	$Cu^{+} + e^- \longrightarrow Cu$	0.521
$Cu^{+} \longrightarrow Cu^{2+} + e^-$	$Cu^{2+} + e^- \longrightarrow Cu^{+}$	0.153

Secondary reactions occur in the electrolyte:

$$2\,Cu^{+} \longrightarrow Cu^{2+} + Cu \text{ (disproportionation)}$$

$$2\,Cu^{+} + 2\,H^{+} + 0.5\,O_2 \longrightarrow 2\,Cu^{2+} + H_2O \text{ (air oxidation)}$$

$$Cu_2O + 2\,H^{+} \longrightarrow 2\,Cu^{+} + H_2O \text{ (dissolution of } Cu_2O)$$

Oxidation by air and disproportionation of copper (I) ions yield a surplus of copper (II) ions in the electrolyte. The copper metal powder formed by the disproportionation of Cu^{+} contributes to the accumulation of the anode slime.

The electrochemical equivalent of copper depends on the oxidation state of the copper:

Species	$g\,A^{-1}\,h^{-1}$	mg/L
Cu^{2+}	1.185	0.3294
Cu^{+}	2.371	0.6588

The greater electrochemical equivalent of copper (I) suggests the use of solutions of copper (I) ions instead of copper (II) ions. However, this concept has not been put into practice because of enormous industrial difficulties [151].

The two most important electrical parameters in electrolytic copper refining operations are the cell voltage and the current density. The cell voltage, which usually ranges between 0.25 and 0.3 V, is determined by several factors:

1) Ohmic resistance of the electrolyte, depending on composition, temperature, electrode distance, and cell construction
2) Polarization, especially concentration polarization of electrodes, which depends on the rate of electrolyte circulation

3) Overpotential because of organic additives (e.g., an *inhibitor* for achieving uniform electrocrystallization of copper)
4) Voltage loss in the circuit
5) Anode passivity, which may occur at high current densities

The interaction of these effects is difficult to predict. At any particular electrolytic facility, a continuing effort is made to optimize parameters that affect the cell voltage. The voltage loss in the conductors and contacts is minimized by good plant design and use of special contacts (Baltimore grooves, Whitehead contacts, wet contacts, etc.).

The second important parameter is the cathodic current density. With increasing current density the production of copper increases and the current efficiency decreases because the cathode potential depends on the current density.

Impurities. The behavior of impurities depends on their position in the electrochemical series: elements more noble than copper are insoluble, while less noble ones dissolve in or react with the electrolyte. For that reason, the anode material is distributed by electrolysis among three phases: cathode copper, electrolyte, and anode slime (Table 18) [152]. Table 19 lists the fractions of anode elements that enter residues and electrolyte.

Copper Cathodes. Cathode copper is produced currently in a purity between 99.97 and 99.99 %. Silver can be deposited in traces; however, this can be avoided by precipitating the silver from the electrolyte with chloride ion. Other impurities, such as suspended slime or droplets of the electrolyte, may be mechanically occluded. The following measures are taken to produce copper of high purity:

1) Maintenance of the optimum current density, to prevent cathodic deposition of other elements (e.g., arsenic)
2) Addition of organic inhibitors to avoid the formation of nodules on the cathode surface
3) Removal of impurities such as arsenic, antimony, and bismuth from the electrolyte by adsorption or chemisorption
4) Prevention or elimination of suspended slimes by regulating the electrolyte flow and occasionally filtering it.

Electrolyte. The composition of copper electrolytes from various plants is generally similar: ca. 35 – 45 g of copper and 150 – 220 g of sulfuric acid per liter at an operating temperature of 55 – 65 °C (see Table 14). As a result of secondary reactions during electrolysis, the concentration of copper (II) ions increases slowly; therefore, this copper surplus must be recovered by cathodic deposition in a few (ca. 2 %) *liberator cells* equipped with insoluble anodes, usually of antimonial lead. Soluble impurities, such as iron, cobalt, zinc, manganese, most of the nickel, and some arsenic and antimony, are also enriched in the electrolyte.

The upper limits of impurity content are ca. 10 g/L for arsenic and 20 – 25 g/L for nickel. Part of the electrolyte is withdrawn continuously from the circuit for purification, and the volume is compensated by adding sulfuric acid and cathode wash water. There are two methods of purification. In the first, the solution can be completely decopperized in a system of special liberator cells with insoluble anodes; arsenic and antimony are almost completely deposited and returned to pyrometallurgical operations. The electrolyte is then concentrated by vacuum evaporation to yield concentrated sulfuric acid and crude nickel sulfate, from which pure nickel sulfate or nickel metal can be produced.

The second method of purification is by producing copper sulfate. For this purpose, the sulfuric acid is usually neutralized by addition of copper shot in the presence of air. The copper sulfate is obtained by crystallization, and the mother liquor is cemented with iron scrap.

Anode Slimes [153], [154]. The content of insoluble substances is < 1 % of the anode weight, and they collect on the bottom of cells as anode slime. They contain precious metals (silver, gold, and platinum); selenides and tellurides of copper and silver; lead sulfate; stannic [tin (IV)] oxide hydrate; and complex compounds of arsenic, antimony, and bismuth (the undesired floating slimes). The main component is copper. In addition, gypsum and silica, alumina, or baryte from anode casting are present.

Table 18. Industrial range of copper anode and cathode compositions

Element	Anodes (%)	Cathodes (%)
Cu	99 – 99.8	99.99 + (excluding oxygen)
O	0.1 – 0.2	not determined
Ag	0.01 – 0.5	0.0005 – 0.002
S	0.0005 – 0.005	0.0004 – 0.001
Ni	0.002 – 0.7	trace – 0.0003
Pb	trace – 0.5	trace – 0.0004
Fe	0.001 – 0.006	0.0001 – 0.0002
Sb	trace – 0.1	trace – 0.0002
As	trace – 0.2	trace – 0.0002
Se	trace – 0.2	trace – 0.0001
Te	trace – 0.03	trace – 0.0001
Bi	trace – 0.03	trace – 0.0001
Au	trace – 0.004	trace

Table 19. Fractions of anode elements entering residues and electrolyte

Metal	Percentage into anode residues	Percentage into electrolyte
Cu	< 0.2	> 99.8
Au	99	< 1
Ag	98	2
Se and Te	98	2
Pb	98	2
Sb	50	50
As	30	70
Co	5	95
Ni	5	95
Fe	0	ca. 100
Zn	0	ca. 100
Bi *		

* Dissolves up to about 0.15 – 0.2 kg m^3 in electrolyte, then forms slimes.

The distribution of the elements (in %) varies over wide ranges:

copper	20 – 50
nickel	0.5 – 2
lead	5 – 10
arsenic	0.5 – 5
antimony	0.5 – 5
bismuth	0.5 – 2
selenium	5 – 20
tellurium	1 – 4
silver	≤ 25
gold	≤ 4

Although the separation techniques differ greatly from plant to plant, anode slimes are generally treated as follows:

1) Oxidizing leaching of copper with dilute sulfuric acid
2) Recovery of selenium and tellurium by pyrometallurgical or hydrometallurgical methods
3) Removal of detrimental elements and production of silver alloy (Doré bullion)
4) Separation of precious metals by electrolysis (silver and gold) and fractional precipitation (platinum metals)

The greatest part of the world selenium production comes from processing copper anode slimes.

6.2.2. Practice of Electrorefining [155–157]

Electrorefining is carried out in large tankhouses with capacities up to 500 000 t/a of pure cathode copper. Today two techniques with principally different starting cathode sheets are used. The conventional system uses thin copper sheets, while the modern systems (ISA developed by Copper Refineries [167], Australia and Kidd developed by Kidd Creek Divison, Falconbridge, Canada) utilize permanent stainless steel cathode sheets. The cathode copper is stripped mechanically from the steel sheets, which are used again, while copper starting sheets have to be prepared for each cathode. The advantages of the permanent cathode systems are high degree of automation, very low personnel costs, higher specific production rate, and higher cathode quality (lower content of impurities, e.g., lead).

Cells and Operation. The cells or electrolytic tanks are constructed of reinforced concrete lined with antimonial lead sheet or with flexible poly(vinyl chloride) or of polymer concrete without a lining. The cells are rectangular, 3.5 – 6 m long, 0.8 – 1.2 m wide and 1.2 – 1.5 m deep. Copper anodes and starting sheet cathodes are suspended alternately in the cells with precise spacing by overhead crane. In most refineries the anodes are prepared (pressed to make them uniformly flat and weighed) before they are inserted into the cells. Commercial cells contain between 40 and 60 electrodes of each type. The distance between the surfaces of the two adjacent electrodes should be small (about 2 cm) to avoid voltage loss, but not so small that the deposited copper is contaminated with anode slime. Electrolyte is circulated through each cell at ca. 0.02 m^3/min. At this flow rate the elec-

trolyte in one cell is exchanged every 5 – 6 h, which is important for removing impurities from the cell.

The anodes remain in the cell for 20 – 28 d. During this time the cathodes are usually changed two or three times, so that their weight is only 60 – 160 kg. The cathodes are removed by crane and the electrolyte on their surface is washed off with hot water. In tankhouses which use stainless steel sheets, the plated copper is stripped mechanically (automatic stripping machine) from both sides of the blank. In conventional tankhouses copper starter sheets are prepared by electrodeposition of copper on titanium sheets (< 1 mm, about 1 d) in special stripper cells. Then the copper sheets are attached to rolled copper support bars for hanging in the cells. This process is partly mechanized [164].

About 15 % of the anode is not dissolved during the refining process. This anode scrap is recycled to the smelter (converter or shaft furnace). The anode slime of the complete cycle is drained, filtered, washed, and sent to the precious metal plant. Part of the electrolyte is removed continuously from the circulation system for purifying. The sulfuric acid is sent back to the tankhouse.

Electrical System. The anodes and cathodes in a cell are connected in parallel. The cells are connected in series to form sections of 20 to 40 cells. Each section can be isolated electrically for inserting or removing anodes or cathodes. For example, 12 sections are connected with one silicon controlled rectifier for current input. Total electrical current through the cell is between 10 000 and 40 000 A. Electrical densities of up to 40 kA/m^2 are used in ISA tankhouses today. To obtain a high current efficiency of 92 – 98 %, the bath and section voltages are monitored [254], [255], and the temperature of the cells is measured by infrared techniques (from the crane). In this way short circuits, caused, for example, by the growth of copper nodules can be quickly detected and corrected. The energy consumption of electrorefining per tonne of plated copper is about 260 – 280 kW h.

Electrocrystallization [163]. The structure of an electrodeposited cathode surface can be influenced by adsorption of molecules on the crystallites. The addition of colloids or special organic compounds improves cathode quality by yielding an evenly grained copper deposition. Important surface-active additives, or inhibitors, are bone glue, gelatin, avitone A (sulfonated aliphatic hydrocarbons), goulac, or bindarene (sulfonated wood fibers). Effective substances with definite composition are thiourea and its derivatives and other sulfur – nitrogen compounds. These inhibitors, mostly in combination, are added to the electrolyte in extremely small amounts, although more is added at higher current density. Inhibitors increase the voltage and, therefore, the energy consumption. Several refineries automatically control their reagent addition rates by measuring glue and thiourea, for example, with the CollaMat [254–256] system. This stabilizes refinery operation and optimizes the process (lower energy consumption).

Special Developments. Jumbo tanks instead of conventional cells, first installed in 1972 at Onahama Tankhouse, Japan [165]. The jumbo tanks have about 20 times the volume of conventional cells. The electrolyte flows parallel to the electrode surface, in contrast to conventional cells. A newer installation of jumbo tanks is the Kidd Creek tankhouse in Canada.

To overcome anodic passivation caused by high current density and impure anodes a periodic current reversal system (PCR) [166] was developed. Optimum reversal conditions seem to be 20 units forward time and 1 unit reverse time [257]. This system has been adopted in some refineries, but due to the extra energy costs it is not widely used.

6.3. Melting and Casting

Copper cathodes must be remelted and cast to shapes because the structure of copper formed by electrocrystallization is not suitable for working to semifinished products. Cathodes are remelted in several types of special furnaces that perform the tasks of melting, postrefining (if necessary), holding, and casting. Casting can be carried out by the older discontinuous methods or by modern continuous casting.

6.3.1. Remelting of Cathodes

There are various kinds of furnaces that use either fossil fuels (coal, coke, fuel oil, natural gas, or reformed natural gas) or electric energy:

Small coke-fired crucible furnaces
Gas- or oil-fired rotary furnaces
Large hearth furnaces (reverbs)
Electric-arc furnaces
Low-frequency induction furnaces
Cathode shaft furnaces (e.g., ASARCO type)

Copper ready for pouring must be nearly free of sulfur, at most 10^{-3} % (10 ppm) S, because a higher content affects detrimentally the mechanical properties of the metal.

In practice, copper is treated in two ways:

1) After melting cathodes with sulfur-containing fuels, the copper melt must be fire-refined like blister copper, by oxidation and poling. This is the case when hearth furnaces are employed for casting.
2) Use of electric power or sulfur-free fuels allows the use of continuous units, such as induction or ASARCO furnaces.

The *ASARCO shaft furnace,* constructed by American Smelting and Refining Co. [168], [169], has a cylindrical shaft consisting of a steel jacket with a brick lining. Cathodes are charged near the top, and the combustion gases ascend in countercurrent flow from groups of burners; the liquid metal is collected in a holding furnace. Apart from its effectiveness and high productivity, a distinct advantage is the maintenance of a constant, slightly reducing atmosphere by automatic control. The largest types (1.8 m diameter and 8 m high) can have a throughput up to 80 t/h. Worldwide ca. 200 units are in operation.

6.3.2. Discontinuous Casting

The discontinuous casting of various shapes on horizontal casting wheels with open ingot molds, analogous to the casting of anodes, was formerly the most important casting method. It is being replaced by continuous casting processes.

6.3.3. Continuous Casting

Since the end of World War II, several continuous casting methods have been developed. A comprehensive synopsis, including patents, has been published [171].

Continuous casting has several technological and economic advantages over the older casting processes, such as excellent surface quality, uniform grain structure without blisters and shrinkage cavities, and energy savings.

Molten copper flows continuously into a relatively short water-cooled chill, usually lined with graphite and open at both top and bottom. The solidifying metal itself forms the lower closure. The shape is steadily withdrawn by clamping rolls and cooled by spraying with water.

There are three main continuously cast shapes: circular billets with a diameter up to 500 mm (for extrusion presses or tube rolling mills), square bars, and rectangular cakes with cross sections up to 1300 × 200 mm (for rolling to sheets and strips). Seamless tubes and other hollow shapes are occasionally produced. Continuous casting shapes are automatically sawn off by flying saws when they reach the required lengths (up to 7.5 m). In semicontinuous casting, the process must be interrupted, but the shapes can be up to ca. 12 m long.

The kind of chill is generally independent of the furnace: the liquid metal stream free-falls into the chill (e.g., Junghans system), or the less frequent fixed connection of chill with the furnace (e.g., ASARCO casting system).

Other methods employ a joint moving in unison with the solidifying metal and a mold with traveling parts forming a gap of the required cross section. (An example is the Hazelett process employed for continuous casting of anodes. Section 6.1.3.) Such casting methods are particularly suitable for continuous production of shapes with a small cross section. Section 6.3.4.

6.3.4. Continuous Rod Casting and Rolling

The continuous production of cast and rolled wire rod [172], [173] involves considerable energy savings because the solidified hot metal can be rolled immediately. Several plants use such a direct process starting from molten electrolytic tough-pitch copper. Worldwide >100 plants are in operation, using the following systems:

1) Properzi process [174]. The first continuous copper rod caster was constructed in 1960 following developments for other nonferrous metals. It operates on the wheel – belt casting principle, i.e., casting into the gap between the periphery of the casting wheel and the closing steel belt. About ten plants are in operation with a capacity up to 30 t/h.
2) Southwire process [175]. Started in 1963 as a further development of the wheel – belt casting principle with capacity up to ca. 50 t/h, the Southwire process directly introduces the continuous cast bar into the rolling mill (Fig. 33). After rolling, the rod, which is oxidized on the surface, is continuously treated by pickling with dilute sulfuric acid or alcohols, water or steam rinsing, and wax coating. The saleable product (8 – 20 mm diameter) is formed into "coils" of up to 10 t, which are packaged. About 30 plants exist at present.
3) Secor process [177]. Only two factories (Australia and Spain) use this modified wheel – belt casting concept, dating from 1975, with a capacity up to ca. 10 t/h.
4) Contirod or Krupp – Hazelett process [178]. As a variant of the Hazelett twin-belt process similar to the Contilanod process (Section 6.1.3.), the continuous cast bar solidifies between two belts and damblock chains and is directly moved to the rolling mill (Fig. 33). Metallurgie Hoboken-Overpelt, Belgium, developed this system in the 1960s; the capacity of the largest units is ca. 50 t/h. At present about 20 plants are operated.
5) General Electric dip forming process [179]. A process based on the "candlestick" principle has been operated since about 1970. A copper core rod is pulled upward through liquid copper so that its diameter increases; the thickened rod moves immediately to rolling. Oxygen-free copper can be produced by using a reducing atmosphere. The capacity is ca. 10 t/h. Nearly 20 plants exist at present.
6) Outokumpu up-cast process [180]. A new upward casting system developed in 1969 draws copper upward through a vertical die cooler with a cooled graphite mouthpiece dipping into the melt. The caster, comprising 8 or 12 strands, yields oxygen-free copper at the rate of ca. 2 t/h per line. Because of the small cross section (8 – 25 mm diameter), hot rolling is not required. Approximately 40 plants are in operation.

6.4. Copper Powder

Copper and copper-alloy powders are required for products prepared by powder metallurgical techniques, including friction materials, carbon brushes, self-lubricating bronze bearings, special filters, and catalysts and other sintered components.

The principal methods for producing copper powders are electrolytic deposition at high current densities and the atomization of molten metal, the latter more for copper-alloy powders. Copper powders are also formed by cementation or by pressurized precipitation from aqueous solutions, but such precipitates are of little commercial interest.

Atomizing is done by spraying a melt into a pressurized air or water flow. Various grain shapes are formed, depending on the cooling rate and on additives that change the surface tension. Additives that decrease surface tension, e.g., magnesium, form irregular powders; those that increase it, e.g., lead or phosphorus, yield globular particles. Spongy powders can be obtained by reduction of oxidized copper powders with hydrogen.

Electrolytically deposited powder particles have dendritic shape; a typical flow sheet is shown in Figure 34. For this purpose electrolysis is used as a shaping process rather than for refining because high-purity copper cathodes are the anodes. The main parameters of powder electrolysis are, as Figure 35 shows, the following [181]:

Cathodic current density
Electrolyte temperature
Concentration of copper (II) ions
Concentration of chloride ions

Varying these factors markedly change particle shapes and apparent densities.

Anodic and cathodic current densities differ. The former is normally 300 – 600 A/m^2, and the latter is 2000 – 4000 A/m^2, which is 10 – 20 times higher than the cathodic values in conventional electrolytic copper refining. This effect is obtained by using copper rod cathodes and plate-like anodes. The energy consumption in powder

electrolysis averages nearly $2\,\mathrm{kWh\,kg^{-1}}$. The powders are generally posttreated for various purposes. Electrolytic copper powders are characterized by dendritic particle shape, high purity, low oxygen content, favorable resistance to oxidation, and good green strength.

During the last 5 years the electrowinning technology to produce copper powder was developed to commercial scale. By using pregnant leach solution from ore leaching operation and subsequent solvent extraction and electrowinning in specially designed cells, it is possible to produce dendritic shape copper powder with well defined parameters like particle size [258].

6.5. Copper Grades and Standardization

The three main grades of refined copper are (1) tough-pitch copper, (2) deoxidized copper, and (3) oxygen-free copper.

Without regard to the method of refining, *tough-pitch copper* normally contains 0.02–0.04 wt % O (as Cu_2O) and ca. 0.01 wt % total of other impurities. This grade is easily worked and has an electrical conductivity of $\geqq 100$ % IACS, but it is unsuitable for welding and brazing because of the danger of hydrogen embrittlement. About 80 % of the world production of refined copper is tough pitch, mostly electrolytic tough-pitch copper (ETP).

Deoxidized copper, with no oxygen content is produced by addition of nonmetallic or metallic reducing agents, usually copper phosphide. As a result of the absence of oxygen, hydrogen embrittlement cannot occur, and such copper is well suited for welding and brazing. The content of residual phosphorus, however, increases the electrical resistivity. Deoxidized copper with low residual phosphorus (DLP, ca. 0.005 % P) is required if the metal is to be used as a conductor. Copper with high residual phosphorus (DHP,

Figure 34. Flow sheet for electrolytic copper powder production [181]

Other conditions: A) Cu 6 g/L, no Cl, 60 °C; B) Cu 17 g/L, no Cl, 3600 A/m^2; C) no Cl, 50 °C, 3600 A/m^2; D) Cu 13 g/L, 50 °C, 3600 A/m^2

ca. 0.04 % P) can be employed for nonelectrical purposes.

Oxygen-free (OF) copper is a special quality produced by keeping oxygen away from the copper melt in a controlled atmosphere. Copper of this type with an oxygen content less than 0.001 wt %, is suited for purposes requiring weldability and high electrical conductivity, especially electronics. OFHC, oxygen-free high-conductivity copper, is internationally known.

Standardization [14], [182], [183]. Most industrial countries have established standards for copper; these national specifications include detailed specifications for chemical composition, physical properties, and geometrical dimensions, but differences exist. Table 20 indicates the rough equivalent between international and European specifications for the most important copper properties.

6.6. Quality Control and Analysis

Tests for quality control of copper are carried out on samples of both refinery shapes and semifinished products. There is need to standardize the testing methods, but currently only some of them are fixed in national specifications. The most important tests are the measurement of electrical conductivity, mechanical properties, and quality of the metal surface.

Table 20. Comparison of international and selected national standards

International ISO R 1337	European EN prEN 1977 prEN 1978	Materials Number prEN 1412	Composition, %				Electric conductivity, % IACS	Remarks
			Cu min	O_2 max	P min	P max		
Cu-CATH1	Cu-CATH1	CR001A	99.99					higher grade cathodes
Cu-CATH2	Cu-CATH2	CR002A	99.9					standard cathodes

Cu-OF1	Cu-OF1	CW007A	99.99				101	oxygen-free copper
Copper not produced from Cu-CATH-1 Cathodes:								
Cu-ETP	Cu-ETP	CR/CW004A	99.99	0.04			100	electrolytically refined tough pitch copper
Cu-FRHC	Cu-FRHC	CR/CW005A	99.99	0.04			100	fire-refined tough pitch copper
Cu-OF	Cu-OF	CR/CW008A	99.95				100	oxygen-free copper
Cu-FRTP	Cu-FRTP	CR/CW006A	99.9	0.1				fire-refined copper
Phosphor containing Copper:								
Cu-PHC	Cu-PHC	CR/CW020A	99.95		0.001	0.006	100	
Cu-HCP	Cu-HCP	CR/CW021A	99.95		0.002	0.007	98.3	
Cu-DLP	Cu-DLP	CR/CW023A	99.9		0.005	0.013		deoxidized copper with low P content
Cu-DHP	Cu-DHP	CR/CW024A	99.9		0.015	0.04		deoxidized copper with high P content

The *electrical conductivity* is very sensitive to impurities and crystal lattice imperfections. *Mechanical tests* measure hardness, tensile strength, elongation at failure, and torsional fatigue strength. The spiral elongation test [184] is a complicated test method that assesses the purity and the mechanical behavior of the sample. Defects on the *surface* and subsurface can occur in various forms, e.g., folds, splashes, cracks, inclusions, and voids. The voids are caused by gas porosity, shrinkage porosity, and shrinkage cavities.

Nondestructive testing procedures, such as radiography, ultrasonic examination, or the eddy-current technique can be used. Metallographic methods (polishing and etching) give information by microscopic examination.

Analytical methods are of interest for determining the impurity level of copper products. Both wet chemical procedures and physicochemical procedures, such as atomic absorption spectrometry, optical emission spectroscopy, and X-ray fluorescence spectroscopy, are employed, the latter essentially for quick analysis of solid and liquid co- and byproducts [185], [186]. The classical analytical methods are gradually being superseded by the modern automatic instrumental techniques. It is especially important to analyze the oxygen content, and one effective modernized method is available, hot extraction, i.e., melting a copper sample in a small graphite crucible and determining the CO formed by IR absorption spectroscopy.

7. Processing and Uses

The pure metal produced in refineries or remelting plants is manufactured into semifabricated products.

7.1. Working Processes

Usually copper is treated initially by noncutting, shaping processes to obtain semifinished products or "semis". These processes are subdivided into hot working, cold working and, if necessary, process annealing.

Hot working means plastic forming above the recrystallization temperature. Generally copper is preheated to 800 – 900 °C, and the subsequent hot forming is finished at ca. 400 °C. Cast bars from modern combined continuous casting/rod-rolling systems already have sufficient temperature, thus saving thermal energy. After cooling, the hot-worked copper is *soft copper*. Its

mechanical and electrical properties are scarcely changed, but its density has increased to nearly 8.9 g/cm^3.

The next step is *cold working*, which involves plastic forming below the recrystallization temperature. In practice, the operation is done at room temperature. Unlike hot working, this procedure entails an essential strain hardening of the metal by increasing the number of lattice defects; however, simultaneously formed lattice voids cause a considerable decrease of electrical and thermal conductivity. After cold working, the metal is *hard copper*.

Process annealing is a heat treatment that is necessary if the hardened copper must be softened again, either for continued working or for producing (soft) copper with high electrical conductivity. Special furnaces are used for the purpose of steady heating and cooling of the metal – often in a nonoxidizing atmosphere. To achieve the intended microstructural change, the recrystallization temperature of 200 – 300 °C must be exceeded; in practice, the metal is heated to 400 – 500 °C for accelerated recrystallization. Copper products with exactly defined properties can be obtained if all annealing conditions are carefully controlled.

Table 21. Important fabricating processes for copper products

Refinery shapes	Hot-working process		Cold-working process	Semi-finished products
Cakes	hot rolling	→	cold rolling	sheets/strip
Rod		⟶	wire drawing	wires
Billets	extruding	→	cold drawing	rods/sections
Billets	extruding	→	cold drawing	tubes/pipes
		↗↘		
	or hot rotary piercing	→	or cold pilger rolling	

The engineering techniques are versatile. The following working methods are of special importance:

hot working	cold working
hot rolling	cold rolling
extrusion	cold drawing
drop forging	cupping

Foils only ca. 0.002 mm thick are manufactured by rolling, and wires to 0.004 mm diameter by drawing. Many products of varying size are fabricated by modern variants of the extrusion process [187]. The fabrication of tubes is also quite diverse [188]. The most widely used working processes are compiled in Table 21.

7.2. Other Fabricating Methods

In many cases, machining operations are required, e.g., cutting, turning, planing, drilling, and sawing. However, these are more important for copper alloys than for pure copper because of copper's tendency to gum. Noncontinuous casting processes are likewise more suitable for copper alloys because copper has a disadvantageous coolability. These include sand mold casting, permanent mold casting, gravity die casting, pressure die casting, and centrifugal casting. Continuous or semicontinuous casting processes, however, are well-suited for pure copper.

Galvanoplasty is an electrolytic operation for manufacturing complicated objects that require high precision and flawless surfaces such as hollow bodies, disk matrices, and electrotypes. A special galvanic method is copper plating, which involves electrolytic deposition of a thin layer of copper on another metal either for surface protection or as a base layer for electroplating with another metal (→ Electrochemical and Chemical Deposition).

Powder-metallurgical techniques are used primarily for the mass production of small pieces, especially intricate forms such as electrotechnical and mechanical structural parts. The metal powders are first compacted by pressure and then sintered in a controlled atmosphere. The copper powder is often mixed with other powdered metals, including those that do not form common copper alloys (→ Powder Metallurgy and Sintered Materials).

There are other important fabricating methods [189]. Joining is usually carried out above room temperature by soldering, brazing, or welding. Soldering may be used for all sorts of copper, owing to the low temperature. However, welding and brazing are feasible only with deoxidized or oxygen-free copper.

When tough-pitch copper is heated in an atmosphere containing hydrogen, the steam generated (see page 7) collects within the grain boundaries at high pressure and can destroy the grain

structure by forming cracks. This phenomenon is known as "hydrogen embrittlement."

Mechanical joining and metal bonding are also possible ways of joining copper with other materials.

Surface treatment of copper is a group of operations for surface protection or surface refinement. These include mechanical, electrical, or electrochemical handling, e.g., polishing, matte finishing, pickling by dilute sulfuric or nitric acid, metal coating or electroplating (with nickel, nickel and chromium, tin, silver, gold, or platinum metals), lacquering or coating with synthetic plastics (mainly for electrical insulation), enameling of objects (applied art), and chemical or electrochemical coloring (decoration). Coloration is effected by chemicals, mostly specially formulated metal salt solutions which form thin layers of insoluble green, red, brown, or black compounds.

7.3. Uses

Copper is a useful material with a wide range of applications because of its combination of properties. Because of its excellent electrical conductivity, it is the dominant conductor material. Copper is used primarily as round wire or rods, bare or insulated, for current generation, transmission, and conduction; various sorts of cables are produced for special applications. Substantial quantities of copper are made into generators, motors, transformers, and other electrical appliances. About 40 % of the world consumption of copper is for electrical purposes. As a result of its high thermal conductivity, copper is well-suited for vessels and pipes, especially for heating, cooling, and heat exchange.

While high-conductivity copper is required for electrotechnical and electronic uses, special copper qualities are chosen for other uses. About 30 % of world copper production is used for alloying. Copper alloys are usually cold-worked; only ca. 10 % of them are cast.

Copper is frequently used in the chemical and food industries because of its high resistance to corrosion. There is substantial use of copper in mechanical engineering, by fabricators of precision implements, in vehicle construction, and in ship building. There is increasing interest in copper building construction as a material for installation, wall lining, and roofing. Hydraulic engineers use copper sheets for tightening on dams, sluices (floodgates), and bridges.

Other areas of application are in the fabrication of household articles, art objects, coins and medals, and in military hardware as ammunition. There is a smaller demand for other purposes, such as electrodeposition; powder-metallurgical copper, special materials for brakes and self-lubricating bearings, small precision parts, filters, graphite brushes; and alloying additives for aluminum, iron, and steel. Use in copper compounds, chiefly copper sulfate and copper oxides, consumes only 1 – 2 % of the primary world production.

Table 22 lists the distribution of copper consumption among various industries.

Table 22. Industrial use of copper (including alloys) in the Western world in 1995, percentage by country [190]

Branch	United States	Europe	Asia
Electrical and electronic industry	25	37.5	50
Industrial machinery and equipment	11	9	9
Building construction	43	39.5	15
Transportation	9	6.5	11
Consumer and general products	12	7.5	15

Substitution and Miniaturization. Several materials compete with copper and may substitute for it, depending on the relative costs. Copper is partly replaced by aluminum in automotive radiators and in transmission cables, high-voltage long-distance lines, and household wiring. Copper wires and cables for telecommunications are being displaced by microwave technology and fiber optics. Copper is being replaced by plastics for water pipes in both residential and commercial construction. In the area of corrosion-resistant materials, in addition to plastics there are also stainless steel and titanium.

The movement toward making smaller and smaller parts has been one of the most pervasive and continuing pressures on the copper market. A dramatic drop in the use of copper has occurred in the widespread acceptance of printed circuits. The use of wire has plummeted. The number and size of the connectors have dropped. On the other hand, miniaturization has steadily

decreased the cost of the final products, thus increasing the number of units sold.

At the same time, however, this drive towards miniaturization, whether in the thickness of an automotive radiator or in the size of an electronic component, is a challenge to the copper industry to produce purer copper and more useful alloys and to the copper fabricating industry to produce the new miniaturized products.

In several applications copper is resisting substitution by using new technologies. For example in telecommunications, copper continues to be the preferred signal carrier for the last mile. The new xDSL (Digital Subscriber Line) technology allows the existing copper infrastructure of ordinary telephone wires to also carry high-speed data. The installation of optical fiber in communication trunk lines has led to a revolution in the telecom industry. Copper application was partly displaced, but overall this increased the demand for copper. Another development is the use of copper circuitry in silicon chip technology, which makes the microprocessors faster and lowers energy consumption. Another example is the automobile radiator, which was formerly made of copper, which was then displaced by aluminum. New technology was developed for producing smaller and lighter copper brass radiators with higher thermal conductivity than aluminum radiators. A final example for innovation in copper is the development of superconducting power cables made from high-temperature superconductor wire. This technology will improve energy efficiency, and now projects in Chicago and Tokyo have been started.

8. Economic Aspects

There are numerous tabular compilations of statistics on copper resources, production, and consumption [192–196]. Many books deal with economic relations and commercial problems, e.g., [197–200]. Compilations of companies in the nonferrous metal industry [201] and the mining industry [202] are published at irregular intervals.

Production and Consumption. The copper production of mines, smelters, and refineries and the consumption by country and region are given in Table 23. Over the decades, the annual per capita consumption of primary copper in the United States has grown [195]:

Late twenties	7.5 kg
Early thirties	2.5 kg
World War II	9.5 kg
Postwar period	7.5 kg
1970	13.3 kg
1979	14.6 kg

During the 1980s, there has been no increase in consumption in America and Europe and only a small increase worldwide. In the 1990s copper production increased due to industrial growth.

Figure 36 shows the development of world per capita consumption for 1950 to 1997.

Cost of Copper Production and Copper Price. The cost of copper production is characterized by high capital investment in mining projects and in smelters and refineries. Mining projects are financed by large consortiums and banks. The capital investment for a green-fields smelter is in the region of 2500 – 3000 $/t of design copper production. Smelter enlargement investment is approximately half that. Therefore, increased smelter production is preferably achieved by enlargement.

In the last 15 years copper leaching projects have been established. This is due to lower capital investment than smelters (about half), and also leaching operations built to increases the copper yield of ores.

Operational costs are high due to energy consumption, which is the most important factor. For primary copper production the overall energy consumption per tonne of copper is about 45 GJ, about half of which is consumed in mining and beneficiation and the rest in smelting and electrorefining. For secondary copper, coming for example from copper scrap smelting and refining, the overall energy consumption is only 20 GJ/t.

Due to several smelter enlargements, leaching operations, and also new energy-efficient milling and smelting/refining processes, the overall production cost of copper are falling.

The copper price is set primarily at the two metal exchanges: the London Metal Exchange (LME) and the New York Commodity Exchange (COMEX). Like the copper production cost also the copper prices have been in an overall declining trend since the World War II. The copper

price also increases and decreases in the same economic cycles as industrial growth and recession. The development of copper prices since 1960 is shown in Figure 37.

Product Information. Information on recent developments in copper are available at http://www.copper.org and http://www.kupfer.org. Statistical data are available at http://www.icsg.org.

9. Environmental Protection

The worldwide growth of industry and population has caused a series of environmental problems, particularly the following: (1) emission control; (2) water protection; (3) solid-waste disposal.

Emission Control. There are two important tasks in the treatment of off-gas from pyrometallurgical processes in copper metallurgy: the removal of sulfur dioxide and the containment of flue dust.

Because most copper comes from sulfide ores, *sulfur* is the main problem in copper extraction. In pyrometallurgical operations, it appears as sulfur dioxide (Table 24) [204], [205]. The mass ratio of sulfur to copper in sulfidic concentrates is usually between 0.8 and 1.6. Consequently, a large quantity of sulfur dioxide must be captured because of its harmful effects on health, vegetation, and property. In most cases, sulfuric acid is produced from the SO_2-containing off-gas (→ Sulfuric Acid and Sulfur Trioxide) [206].

Table 24. Comparison of SO_2 concentrations in copper smelting off-gas [203]

Process	SO_2, vol %
Multiple-hearth roasting	5 – 8
Fluidized-bed roasting	8 – 15
Sinter roasting	1 – 2
Blast furnace smelting	2 – 5
Reverberatory furnace smelting	0.5 – 2.5
Electric furnace smelting	0.5 – 5
Outokumpu flash smelting	10 – 30
INCO flash smelting	75 – 80
KIVCET process	80 – 85
Peirce – Smith converter	5 – 12
Hoboken converter	7 – 17
TBRC process	1 – 15
Mitsubishi process	15 – 20
Noranda process	10 – 20

Flue dust can be separated from off-gas to a high degree in modern gas-cleaning systems such as electrostatic precipitators, baghouses, cyclones, and wet scrubbers. This metal-containing dust is recycled.

Water Protection. Harmful wastewater does not usually result from pyrometallurgical copper production but water for direct or indirect cooling of furnaces, casting machines, and cast copper products is required on a large scale. This cooling water is moderately warmed, but does not acquire chemical impurities. Closed

Figure 37. Development of copper prices since 1960
a) Cu price (current); b) Cu price (constant 1996)

circulation is used as much as possible in modern plants.

Hydrometallurgical operations for the extraction of copper from ores or concentrates present the risk of water pollution. These solutions, of various compositions, must be posttreated if they cannot be recycled. Such posttreatment consists of neutralization or precipitation of specific ions, chiefly anions bearing sulfur and the cations of heavy metals. Lime is an excellent precipitant. Thus, the sulfate ion in sulfuric acid solutions formed during hydrometallurgical extraction is precipitated as gypsum [208].

Solid-Waste Disposal. The following means are used for handling solid residues:

1) Recycling
2) Exploitation as raw material for the preparation of useful products
3) Dumping in deposits

One example of each method follows:

1) Flue dust from pyrometallurgical operations, e.g., from the Outokumpu flash smelting process, are added to the feed and recycled into suitable furnaces (Section 5.5.1) and occasionally into blast furnaces after agglomeration (Section 5.4.1). Zinc-containing flue dusts can be processed into zinc and zinc compounds.
2) Discarded slags with low copper content from some copper smelting processes can be sold after suitable treatment (Section 5.3.3).
3) Hydrometallurgical techniques yield various precipitates such as elemental sulfur or impure gypsum, which can easily be deposited.

10. Toxicology

Copper is a vital trace element for humans, most animals, and plants. The copper content of an adult human ranges from 50 to 120 mg. The average dietary intake of copper by adults ranges from 0.9 to 2.2 mg/d. For higher organisms, the compact metal is completely harmless. However Protista, especially bacteria, die in contact with metallic surfaces of copper and many of its alloys (oligodynamic effect) [209], [210].

Continued exposure to the metal dust or fumes can irritate mucous membranes. The following exposure limits have been established:

Form	Federal Republic of Germany	United States
Metal dust	MAK 1 mg/m^3	TLV/STEL 2 mg/m^3
Metal fumes	MAK 0.1 mg/m^3	TLV/TWA 0.2 mg/m^3

1. Introduction

Copper alloys are of ancient origin, being the source of tools that led humans from the Stone Age into the Bronze Age. Over the centuries, people have learned to refine metals to a more pure state and alloy these metals together to form a more useful product.

As techniques improved, the number of copper alloys proliferated and became more complicated. In parallel, the alloy systems of other metals were also evolving and increasing in number. Each manufacturer had devised a nomenclature that was specifically applicable to his alloys, making it difficult for users to purchase from more than one source and still obtain equivalent products.

In the mid-1950s, the Aluminum Association established a four-digit numbering system to define the various aluminum alloys. The steel industry already had a four-digit system to describe many of its alloys. In the mid-1960s, the copper industry decided to adopt a three-digit system. There was a spurt of research activity in the copper industry, especially on aluminum bronzes, which became difficult to administer with the three-digit alloy identification system. Efforts were also being made internationally to develop a unified method of systematically identifying alloys. In the United States, a *Unified Numbering System* (UNS) was devised, while in Europe the International Standards Organization (ISO) began assembling an identification system.

The UNS designation system for metals and alloys in North America has been developed under the joint management of the American Society for Testing and Materials (ASTM) and the Society of Automotive Engineers (SAE). This designation system incorporates an alphanumeric identification that encompasses the commercially produced metals and alloys. The International Standards Organization (ISO) uses a designation that is based on composition (e.g., cartridge brass, CuZn3O), but as the number of specific alloying elements increases, the

10.1002/14356007.a07_525

ISO designation becomes unwieldy, e.g., UNS C86300 vs. ISO CuZn25Al6Fe3Mn3.

The initial letter of the UNS system designates the metal and alloy system covered, e.g., A for aluminum and aluminum alloys, P for precious metals and alloys, N for nickel and nickel alloys, or C for copper and copper alloys. The copper and copper alloys system is administered by the Copper Development Association (CDA) and encompasses all coppers and copper alloys of commerical use that have been presented for inclusion in this system. The numeric portion of the alphanumeric UNS system classifies the various alloys into specific subgroupings on the basis of the quantity of copper present and the alloying elements present. These subgroups are identified as follows:

C10000	Wrought coppers
C20000	Wrought copper – zinc alloys (wrought brasses)
C30000	Wrought copper – zinc – lead alloys (wrought leaded brasses)
C40000	Wrought copper – zinc – tin alloys (wrought tin brasses)
C50000	Wrought copper – tin alloys (standard phosphor bronzes), wrought copper – tin – lead alloys (leaded phosphor bronzes), and copper – phosphorus alloys (brazing alloys)
C60000	Wrought speciality alloys: wrought copper – aluminum alloys (aluminum bronzes), wrought copper – silicon alloys (silicon bronzes), and miscellaneous copper – zinc alloys (manganese brasses and aluminum brasses)
C70000	Wrought copper – nickel alloys (cupronickels), wrought copper – nickel – zinc alloys (nickel silvers), wrought leaded copper – nickel – zinc alloys (leaded nickel silvers)
C80000	Cast coppers, cast high-copper alloys, cast copper – tin – zinc alloys, cast copper – tin – zinc – lead alloys (unleaded and leaded red brasses, semi-red brasses, yellow brasses, and manganese brasses), cast copper – zinc – silicon alloys (silicon bronzes and silicon brasses)
C90000	Cast copper – tin alloys (tin bronzes), cast copper – tin – lead alloys (leaded tin bronzes), cast copper – tin – nickel alloys (nickel tin bronzes), cast copper – aluminum – iron and copper – aluminum – iron – nickel alloys (cast aluminum bronzes), cast copper – nickel – iron alloys (copper nickels), cast copper – nickel – zinc alloys (nickel silvers), and cast special alloys

This classification system is the basis for discussing commercial coppers and copper alloys in an orderly manner.

The *relative electrical conductivity* is given in %IACS: In 1913, in France, an electrical standard was adopted on an international basis. A copper wire 1 m long and weighing 1 g, with an electrical resistance of 0.15328 Ω, was selected as the standard. A value of 100 % electrical conductivity was assigned to this wire, which has a volume resistivity of 0.017241 Ω mm^2 m at 20 °C. This is the International Annealed Copper Standard (IACS).

Some coppers may have a greater electrical conductivity than 100 %. Alloy C11000 has 101 % IACS due to its higher purity. Figure 1 illustrates how many of the common elements associated with copper, even at minute levels, degrade the electrical conductivity. Most high-conductivity copper alloys start with electrolytic copper as the basic building block for developing the alloy.

Figure 1. Effect of impurity levels on the electrical conductivity of copper [28, p. 66]

2. Wrought Coppers

The wrought coppers are further subdivided into two classes: (1) the coppers, i.e., copper alloys that are designated as C10000 through C15600 and have a minimum of 99.3 wt % Cu, and (2) high-copper alloys, which are designated as C16000 through C19600 and have a minimum of 96.0 wt % Cu.

2.1. Coppers, ≧ 99.3 % Cu

In coppers, there are several elements that are added for specific purposes and one element that is specifically excluded – oxygen [*7782-44-7*]. Unless special precautions are taken to prevent contact with air when the copper is molten, oxygen is absorbed into the liquid copper. It remains there unless the copper is deoxidized. The presence of oxygen in copper has several deleterious effects:

1) Hydrogen embrittlement is a probability during brazing or welding, or any time copper is heated above 450 °C and hydrogen is present in the atmosphere or environment.
2) The electrical conductivity is somewhat lowered and elements used to deoxidize the copper lower the conductivity even more.
3) Oxides present act as inclusions that reduce formability. Rolling further accentuates the effect of the oxides.
   When the oxides are randomly spaced throughout the matrix, the effect on the formability is relatively low. When processing causes these oxides to agglomerate within the matrix in the form of a string, however, formability is greatly reduced. This condition most often has its origin in the original casting of the alloy, where agglomeration is permitted to begin.
4) Copper oxides within the structure interfere with recrystallization and grain growth during annealing.

The oxygen problem is handled by one of three methods:

1) Processing the liquid copper in such a manner as to exclude oxygen through the use of vacuum chambers or reducing or inert atmospheres during melting, pouring, and casting. However, this does not preclude the absorption of oxygen at some later time (annealing, welding, etc.) unless these same precautions are followed.
2) Using normal melting and casting techniques, but adding deoxidizers to the melt to combine with the oxygen. With excess deoxidizer present, the chemical reaction is driven to completion and offers protection during subsequent processing. The common deoxidizers are phosphorus, boron, zirconium, and magnesium.
3) Recognizing that oxygen is present but working within the limitations imposed by the oxygen during subsequent processing.

Other elements that may be present as impurities are removed normally through fire and electrolytic refining processes, leaving very pure (less than 0.10 % other elements) copper.

In the coppers (≧ 99.3 wt % Cu), several alloying elements are used to provide specific attributes.

Silver [*7440-22-4*] is alloyed with copper to increase the softening temperature of rolled temper products. When silver is present in sufficient quantity, a rolled temper copper can be subjected to higher processing temperatures for longer times without softening the metal excessively. Figures 2 and 3 illustrate the effect of silver content on the softening characteristics of silver-bearing copper strip that has been reduced 40 % in thickness by cold rolling. Figure 2 illustrates that the quantity of silver alloyed with copper affects the amount of softening with time at 290 °C. Figure 3 illustrates the effect at 340 °C for the same group of silver-bearing coppers.

Figure 2. Effect of silver additions (wt %) on the annealing of copper following 40 % cold work [26], [27]
Annealing temperature, 290 °C

Phosphorus [*7723-14-0*] is added to molten copper as a deoxidizer. When normal control of oxygen content is exercised during the melting of copper, a minimum of 0.015 % P should be sufficient to deoxidize the melt completely. The copper should then be capable of passing the standard hydrogen embrittlement tests. Deoxidized high-phosphorus (DHP) copper (C12200) contains 0.015 –0.040 wt % P. Its electrical conductivity is approximately 85 % IACS. The high phosphorus leaves sufficient deoxidizing power to maintain deoxidizing during welding or brazing of the copper. With careful control of oxygen content during melting, a phosphorus residual in the range of 0.004 – 0.012 wt % can be achieved to produce deoxidized low-phosphorus (DLP) copper (C12000). Since part of the phosphorus analyzed is present as oxide, C12000

probably would fail the hydrogen embrittlement tests when the phosphorus is kept low to maximize the electrical conductivity (ca. 95 % ACS). If the phosphorus is kept toward the high side of the phosphorus range to meet the hydrogen embrittlement test standards, the electrical conductivity is reduced to ca. 90 % IACS.

Figure 3. Effect of silver additions (wt %) on the annealing of copper following 40 % cold work [26], [27]
Annealing temperature, 340 °C

Figure 4. The effect of alloying elements on the conductivity of copper [28, p. 91]
Of the elements shown, silver has relatively little effect, whereas phosphorus greatly affects the conductivity.

Figure 4 illustrates the effect on the electrical conductivity of alloying various elements with copper. Phosphorus, which strongly lowers the conductivity, is the most widely used deoxidizer, but other elements can be used, e.g., lithium, sodium, boron, carbon, magnesium, or silicon. Beryllium, aluminum, calcium, manganese, and zinc are also deoxidizers, but they are usually added to copper for other reasons.

Boron [*7440-42-8*] is used as a deoxidizer. *Arsenic* [*7440-38-2*] is alloyed in copper to increase the corrosion resistance and to increase the temperature of recrystallization. Arsenic decreases the electrical conductivity (see Fig. 4). *Cadmium* [*7440-43-9*] is used as an alloying element in copper to increase the strength of the copper and, like silver, to raise the softening temperature. Cadmium lowers the electrical conductivity more than silver (see Fig. 4). Small amounts of tin [*7440-31-5*] may be added to copper as a strengthener. Tin also reduces the electrical conductivity.

Tellurium [*22541-49-7*] is alloyed with copper to increase machinability. The machinability rating of pure copper is 20 FMB (free machining brass (FMB), 100), but addition of tellurium increases the rating to 85 FMB. Tellurium has only a slight effect on electrical conductivity, because it is insoluble in copper in the solid state. Sulfur [*7704-34-9*] is used at times to increase the machinability of copper. Sulfur decreases casting quality by creating gas holes in the casting, making sulfur less desirable than tellurium.

Zirconium [*7440-67-7*] functions as a deoxidizer when added to copper. In fact, it reacts so readily with oxygen that a patented casting technique was developed to make zirconium addition feasible. The residual zirconium alloys with copper. Only a small amount of zirconium is added to the copper, 0.05 – 0.15 wt %. It provides strength through a precipitation hardening effect. The solid solubility of zirconium in copper decreases with decreasing temperature. The zirconium forms an intermetallic compound with copper that is a fine precipitate in the copper matrix. Zirconium copper has 95 % IACS conductivity, a high softening temperature, and good strength and formability. One difficulty in using zirconium is the effect on surface quality. The copper – zirconium precipitate can be large at times. In continued rolling, the precipitate produces a gray copper color at the surface of the strip, leaving a mottled *copper – gray copper* appearance that is undesirable in some applications.

Cobalt [*7440-48-4*] acts as a strengthener in copper, forming a precipitate of fine intermetallic compounds. Where phosphorus is present,

cobalt exhibits an even greater effect on alloy strength. Magnesium [*7439-95-4*] is a strong deoxidizer. It can create porosity problems in casting unless its addition is carefully controlled. As an alloying element, it forms a precipitate of $CuMg_2$ particles and strengthens the copper.

The coppers shown in Table 1 with their compositions and properties are representative of the types frequently used.

In addition to the coppers there is a series of *dispersion-strengthened coppers*, containing various quantities of aluminum oxide [*1344-28-1*], Al_2O_3, as the dispersant. The alloys are manufactured by using powder metallurgical technology, since Al_2O_3 would tend to agglomerate in the liquid phase during conventional casting.

The analytical oxygen content is high for copper standards, reaching 0.59 wt % O. However, the effective content is $\leqq$ 0.04 wt %, the rest of the oxygen being in the Al_2O_3 dispersant. The most popular alloys in this group are described in Table 2.

2.2. High-Copper Alloys, $\geqq$96.0 % Cu

The high-copper alloys ($\geqq$ 96.0 wt % Cu) contain several other alloying elements, as well as some of those in the coppers. Those alloying elements common to both groups are usually present in a greater percentage in the high-copper alloys. The high-copper alloys are grouped with respect to the major alloying element.

Cadmium Coppers. The cadmium coppers (C16200 – C16500) contain cadmium, from 0.6 to 1.2 wt %. The high-cadmium coppers have greater hardness and higher softening temperatures than the coppers with lower cadmium additions. The reduction in electrical conductivity from 96 to 90 % IACS is modest. Tin is an additional strengthener, giving a 15 % strength increase and a reduction to 60 % IACS in electrical conductivity, with no decrease in softening temperature. Table 3 describes the most popular cadmium – copper alloys.

Beryllium Coppers. The beryllium coppers (C17000 – C17700) constitute an alloy family in the high coppers. The addition of up to 2 wt % Be and a small amount (0.6 wt % max.) of cobalt yields one of the highest strength copper alloys (C17200) available, with upward of 1380 MPa ultimate tensile strength. Figure 5 is a partial copper – beryllium phase diagram.

Figure 5. Copper–beryllium phase diagram [28, p. 63]

The very high strength, as in all of the copper – beryllium alloys, is obtained through heat treatment. The metal is subjected to a solution anneal and quenched. A saturated alpha Cu – Be – Co phase is produced. Work hardening the metal in the solutionized condition adds to the total strength obtainable by the subsequent precipitation of intermetallic particles. When the metal has been work-hardened to the extent desired, the metal is given a precipitation heat treatment (aged) and copper cobalt beryllides, (Cu, Co) Be, are precipitated, providing an extremely strong copper alloy. The precipitation process not only strengthens the product, but also increases the electrical conductivity. The electrical conductivity of C17200 can increase from 16 to 22 % IACS during the precipitation heat treatment.

Most of the beryllium – copper alloys are supplied as either *age hardenable* or *mill hardened.* The age-hardenable temper permits the manufacturer to fabricate parts from a relatively ductile material. The precipitation heat treatment is then performed on the fabricated parts to maximize their strength and electrical conductivity. The parts may require fixturing prior to and during the heat treatment to minimize warpage during the treatment cycle. Fabricating parts from mill-hardened metal does not require any further

Table 1. Wrought coppers

UNS (ISO) alloy	Alloying elements[a], wt%	Permissible impurities (max.[b]), wt%	Density, g/cm^3	Description, properties	Uses
C10100	Cu 99.90	P 0.0003 Te 0.0010[c] Hg 0.0001 Cd 0.0001 S 0.0018 Pb 0.0010 Se 0.0010 Bi 0.0010 O_2 0.0010	8.94	oxygen-free electronic; extremely pure copper with very low oxygen formulated for electronic applications where purity is essential to maintain electrical conductivity > 101% IACS as annealed	bus bars, waveguides, anodes, glass-to-metal seals
C10200 (CuOF)	Cu 99.95		8.94	oxygen-free, very pure copper with no residual deoxidants, electrical conductivity of 101% IACS	where the presence of oxygen would decrease deformability in fabricating the required products in transistor components, coaxial cables, klystrons
C10400	Cu + Ag 99.95 Ag 0.027		8.94	oxygen-free with silver added to raise the softening point	similar to C10200 where good creep strength at elevated temperature is essential
C10700	Cu + Ag 99.95 Ag 0.085		8.94	oxygen-free with silver added to raise the softening point	similar to C10400
C10920	Cu + Ag 99.90	O_2 0.02	8.94	low residual oxygen maintained by processing	replaces the more expensive oxygen-free copper and still retains maximum formability and electrical conductivity of 100% IACS
C10940	Cu + Ag 99.90 Ag 0.085	O_2 0.02	8.94	low residual oxygen, alloy C10920 with silver	silver-bearing copper, retains formability and electrical conductivity of 100% IACS with silver to raise the softening point, replaces the more expensive oxygen-free alloys
C11000 (CuETP)	Cu + Ag 99.90	O_2 0.04 nominal	8.94	electrolytic tough pitch, commercially pure copper: quantity of retained oxygen depends on processing, embrittles if heated above 370 °C in hydrogen	electrical wires, nails, switches, terminals, rivets
C11600 (CuAg0.1)	Cu + Ag 99.90 Ag 0.085	O_2 0.04 nominal	8.94	tough-pitch copper with silver, commercially pure copper with silver to raise the softening point	automotive radiator, fin stock, printed circuit foil
C12000 (CuDLP)	Cu + Ag 99.90 P 0.004–0.012		8.94	phosphorus deoxidized, low residual phosphorus, fully deoxidized to meet hydrogen embrittlement tests and maximize electrical conductivity of 95% IACS	electronic connectors, waveguides
C12200 (CuDHP)	Cu + Ag 99.9 P 0.015–0.040		8.94	phosphorus deoxidized, high residual phosphorus, phosphorus retained to protect against hydrogen embrittlement during welding or brazing, electrical conductivity reduced by phosphorus to 85% IACS	water and heat-exchanger tubing and plates

Table 1 Continued

C12800	Cu + Ag 99.88 Ag 0.034	As 0.12 Sb 0.003 Te + Se 0.025 Ni 0.050 Bi 0.003 Pb 0.004	8.9	fire-refined tough pitch with silver, lower grade of copper that has not been electrolytically refined, silver added to raise the softening point	roofing, screening, kettles, and radiator fin stock
C14200 (Cu,As(P))	Cu + Ag 99.4 As 0.15–0.50 P 0.015–0.040		8.94	phosphorus-deoxidized arsenical, electrical conductivity of 45% IACS, an aid in resistance welding, arsenic reduces corrosion	locomotive fireboxes, heat-exchanger and condenser tubes
C14310	Cu + Cd 99.90 Cd 0.10–0.30		8.94	cadmium-deoxidized copper, electrical conductivity of 96% IACS and ability to resist softening and hydrogen embrittlement	anneal-resistant electrical components such as lead frames, contacts, and terminals, furnace-brazed assemblies and components
C14500 (Cu,Te)	Cu + Te 99.90 P 0.004–0.012 Te 0.40–0.7		8.94	phosphorus-deoxidized, tellurium-bearing copper, free-machining copper, electrical conductivity of 93% IACS combined with good machinability and good hydrogen embrittlement, excellent choice when extensive machining is required	electrical connectors, soldering tips, welding tips, parts assembled by furnace brazing
C15000	Cu + Ag 99.80 Zr 0.10–0.20		8.89	zirconium copper: heat-treatable deoxidized copper, electrical conductivity of 93% IACS, good corrosion resistance, good creep strength	electrical switches, high-temperature circuit breakers, solderless wrapped terminals

[a] Minimum, except for ranges. [b] Maximum, except where stated otherwise. [c] Total Se, Te, Bi, As, Sb, Sn, and Mn not to exceed 0.0040 wt%

Table 2. Wrought dispersion-strengthened coppers

UNS (ISO) alloy	Alloying elements*, wt%	Permissible impurities (max.), wt%	Density, g/cm^3	Description, properties	Uses
C15710	Cu + Ag 99.71 Al 0.08–0.12 O_2 0.07–0.15	Fe 0.01 P 0.01	8.82	"glid-cop" alloys, produced through powder metallurgical techniques to obtain rolled strip, wire, rod, and shaped wire with electrical conductivity of 90% IACS	electrical connectors, electronic spring contacts, heat sinks
C15720	Cu + Ag 99.52 Al 0.18–0.22 O_2 0.16–0.24	Fe 0.01 P 0.01	8.81	similar to C15710, where high strength is required and electrical conductivity of 89% IACS is tolerable	lead frames, contact supports, circuit-breaker components
C15735	Cu + Ag 99.24 Al 0.33–0.37 O_2 0.29–0.37	Fe 0.01 P 0.01	8.80	similar to C15710 and C15720, where even higher strength and an electrical conductivity of 85% IACS are retained after exposure to high temperature	resistance-welding electrodes, circuit-breaker components, heat sinks

* Minimum, except for ranges. Aluminum is reported as Al_2O_3 and oxygen is reported as $Al_2O_3 + Cu_2O$.

Table 3. Wrought cadmium coppers

UNS (ISO) alloy	Alloying elements*, wt %	Permissible impurities (max.), wt %	Density, g/cm³	Description, properties	Uses
C16200 (CuCd1)	Cd 0.7–1.2 Cu + Ag + Cd + Fe 99.8 Cu + Ag remainder	Fe 0.02	8.89	cadmium copper, high strength with electrical conductivity of 90% IACS	trolley wire, heating pads, electric-blanket elements, high-strength transmission lines
C16500	Cd 0.6–1.0 Sn 0.5–0.7 Cu + Ag + Cd + Sn + Fe 99.8 Cu + Ag remainder	Fe 0.02	8.89	tin-bearing cadmium copper, higher strength, electrical conductivity of 60% IACS	electrical springs, lead frames, electronic contacts, clips, flat cables

* Minimum, except for ranges.

heat treatment, but strength usually is sacrificed to have sufficient formability for part fabrication.

Beryllium is expensive. Use of the beryllium coppers is prohibited by the cost of the alloys, except where their very high strength, good relaxation, and corrosion resistance are necessary. Although some degrading of the high strength occurs, substitution of more cobalt and nickel for some of the beryllium produces less expensive grades of beryllium copper (C17400, C17410, C17500). One advantage of these lower priced products is that the electrical conductivity is 40 or 60% IACS, rather than 22% IACS. Since these alloys have better formability, they are supplied mill-hardened, eliminating the need for heat treatment after forming.

Where wire and rod are used to form the beryllium–copper components, machinability is often needed. Lead is added, up to 0.6 wt% (C17300), to aid in the machinability. Free machining brass has a *machinability* of 100 FMB, unleaded beryllium copper of 20 FMB, and leaded beryllium copper of 50 FMB. Some producers also add small quantities of tellurium for machinability, but lead gives superior results.

The high temperatures and long time cycles normally employed in the solution heat treatment of beryllium–copper alloys result in relatively large grain sizes, which decrease formability in the thinner products now in use. Some producers add cobalt or increase the amount of cobalt used as a grain refiner with good results. The cobalt also replaces part of the beryllium. New processing techniques are being incorporated to effect a grain size reduction. Table 4 describes the more popular beryllium–copper alloys.

Chromium Coppers. Chromium is added to copper up to 1.2 wt% to provide another family of alloys that are heat treatable (C18000–C18500). In heat treating, intermetallic particles are precipitated to yield a moderately strengthened copper with an ultimate tensile strength of 380 MPa vs. 220 MPa and a moderately high electrical conductivity of 80% IACS vs. 101% IACS for C11000. The chromium that is present not only is a strengthening agent, but also acts as a grain refiner. Some chromium coppers may contain up to 0.8 wt% Si as a substitute for chromium and as an aid in forming a fine precipitate. The more popular chromium–copper alloys are described in Table 5.

Leaded Copper and Specialty Copper Alloys. Alloys C18700–C19100 (UNS) are principally designed for wire and for welding rod products. Within this group, tin and nickel are added to strengthen the copper. For welding, silicon is added to increase the fluidity of the weld metal. Manganese and phosphorus are added to act as deoxidizers. Alloy C18700 has up to 1.5 wt% Pb added for machinability, giving a machinability of 85 FMB. The presence of the lead makes this alloy useful for machinable wire, but not for welding. Alloy C18900 contains tin, silicon, and manganese for strength and fluidity in welding. Alloy C19100 contains nickel, tellurium, and phosphorus, is heat treatable, and

Table 4. Wrought beryllium coppers

UNS (ISO) alloy	Alloying elements, wt%	Permissible impurities (max.), wt%	Density, g/cm³	Description, properties	Uses
C17000 (CuBe1.7-CoNi)	Be 1.60–1.79 Cu + Ag remainder	Ni + Co 0.20 Ni + Co + Fe 0.6 Si 0.20 Al 0.20	8.41	beryllium copper, 165 alloy, heat-treatable, supplied either age hardenable or mill hardened, exhibits hard-temper tensile strength of 1310 MPa with electrical conductivity of 22% IACS	bellows, springs, nonsparking safety tools, lock washers
C17200 (CuBe2-CoNi)	Be 1.80–2.00 Cu + Ag remainder	Ni + Co 0.20 Ni + Co + Fe 0.6 Si 0.20 Al 0.20	8.30	beryllium copper, 25 alloy, heat treatable, normally supplied mill hardened or age hardenable, exhibits hard-temper tensile strength of 1380 MPa with electrical conductivity of 22% IACS	switchblades, diaphragms, contacts, connectors, terminals
C17300 (CuBe2-Pb)	Be 1.80–2.00 Pb 0.20–0.6 Cu + Ag remainder	Ni + Co 0.20 Ni + Co + Fe 0.6 Si 0.20 Al 0.20	8.30	beryllium copper, M 25 alloy (machinable), same properties as C17200 with lead added for machinability (50% vs. 20% for other beryllium coppers), must be heat treated	parts manufactured by screw machine techniques
C17400	Co 0.15–0.35 Be 0.15–0.50 Cu + Ag remainder	Fe 0.20 Si 0.20 Al 0.20	8.80	relatively new beryllium copper, cobalt added as a grain refiner and strengthener, available mill hardened, tensile strength of 800 MPa, electrical conductivity of 40–55% IACS, very good resistance to stress relaxation	electrical and electronic components
C17410	Co 0.35–0.6 Be 0.15–0.50 Cu + Ag remainder	Fe 0.20 Si 0.20 Al 0.20	8.80	relatively new beryllium copper, similar to C17400, tensile strength of 900 MPa, electrical conductivity of 45–60% IACS	same as C17400
C17500 (CuCo2Be)	Co 2.4–2.7 Be 0.40–0.7 Cu + Ag remainder	Fe 0.10 Si 0.20 Al 0.20	8.75	low-beryllium copper, alloy 10, supplied either age hardened or mill hardened, similar to C17400, tensile strength of 900 MPa, electrical conductivity of 45–60% IACS	high-strength electrical contacts

Table 5. Wrought chromium coppers

UNS (ISO) alloy	Alloying elements, wt%	Permissible impurities (max.), wt%	Density, g/cm³	Description, properties	Uses
C18000	Ni(Co) 2.0–3.0 Cr 0.10–0.6 Si 0.40–0.8 Cu + Ag remainder	Fe 0.15	8.89	chromium copper, heat treatable, usually supplied aged	resistance welding electrodes, cable connectors, molds, spot-welding tips
C18200 (CuCr1)	Cr 0.6–1.2 Cu + Ag remainder	Fe 0.10 Si 0.10 Pb 0.05	8.89	chromium copper, heat treatable, usually supplied aged, excellent cold workability, electrical conductivity of 80% IACS	circuit-breaker components, spot-welding tips, electrical and thermal conductors

Table 6. Wrought leaded copper and specialty coppers

UNS (ISO) alloy	Alloying elements, wt%	Permissible impurities (max.), wt%	Density, g/cm³	Description, properties	Uses
C18700 (CuPb1)	Pb 0.8–1.5 Cu + Ag remainder		8.94	leaded copper, lead added to oxygen-free or deoxidized pure copper, electrical conductivity of 96% IACS, machinability of 85%	electrical connectors and screw machine parts requiring high electrical conductivity
C18900	Sn 0.6–0.9 Si 0.15–0.40 Mn 0.10–0.30 Cu + Ag remainder	Pb 0.02 P 0.05 Al 0.01 Zn 0.10	8.91	copper welding wire and rod, alloy strongly deoxidized, good strength but electrical conductivity of only 30% IACS	primarily welding
C19100	Ni 0.9–1.3 Te 0.35–0.6 P 0.15–0.35 Cu + Ag remainder	Fe 0.20 Pb 0.10 Zn 0.50	8.94	heat-treatable machinable copper, fully heat treated, electrical conductivity of 55% IACS, machinability of 75%	bolts, bushings, electrical components, gears, nuts, tie rods

has a machinability of 75 FMB. The leaded copper and specialty copper alloys are in Table 6.

High-Strength Coppers. The last alloy family in the high-copper alloys has iron as the major alloying element. Iron adds strength to the alloys, but dissolving iron in molten copper is a problem. A master alloy of copper and iron aids greatly in putting the iron into solution. These alloys contain phosphorus to deoxidize the melt, and there is a synergistic relationship among the copper, iron, and phosphorus that adds additional strength to the alloy.

The UNS numbers in this alloy series start with the moderate strength C19200, which contains 1 % Fe and 0.025 wt % P. A major alloy in this series is C19400, which contains 2.1–2.6 wt % Fe, with an ultimate tensile strength of 525 MPa in spring temper. During processing, the iron and phosphorus are first solutionized and then precipitated as fine spheroids of copper–iron phosphides. As in other alloys, precipitation of the alloy additions from solution increases the electrical conductivity. When fully solutionized, the alloy has an electrical conductivity as low as 35 % IACS. However, through special processing in which the maximum precipitation has been achieved, the alloy can exhibit an electrical conductivity as high as 75 % IACS. Alloy C19400 also has a small percentage (ca. 0.12 wt %) of zinc for improved control over process annealing.

Alloy C19500 is the next commercially important alloy in the high-copper series. It contains iron, phosphorus, tin, and cobalt as strengtheners and deoxidizers. The precipitation of intermetallic particles of iron, phosphorus, and cobalt is used to gain strength, and the tin is also a solid-solution strengthener. In the annealed, fully precipitated state, the alloy develops an ultimate tensile strength of 410 MPa with an electrical conductivity of 55 % IACS. Through cold work after the precipitation anneal, an ultimate tensile strength in excess of 670 MPa can be attained.

Another alloy in the system of high coppers is C19600, consisting of copper–iron–phosphorus. This alloy is very similar to C19200, except it has slightly higher phosphorus content. Its mechanical properties are similar to those of C19200. The higher phosphorus seems to increase precipitation, so the electrical conductivity is higher.

The high-strength coppers are further described in Table 7.

3. Wrought Brasses

The series of alloys from which a majority of the industry's products are made are the copper–zinc alloys – the brasses (C20000–C29999). The most popular alloy of the group is C26000 (cartridge brass, 70/30 brass).

Table 7. Wrought high-strength coppers

UNS (ISO) alloy	Alloying elements*, wt%	Permissible impurities (max.), wt%	Density, g/cm^3	Description, properties	Uses
C19200	Cu 98.7 Fe 0.8–1.2 P 0.01–0.04		8.87	HC copper iron, a high-strength moderate-conductivity alloy: tubing with electrical conductivity of 50% IACS and hard-drawn tensile strength of 390 MPa, hard-temper strip with electrical conductivity of 60% IACS and tensile strength of 450 MPa	tubing: heat exchangers, automotive hydraulic brake linings strip: electrical connectors, contact springs, lead frames, gaskets, hollowware
C19400	Cu 97.0 Fe 2.1–2.6 Zn 0.05–0.20 P 0.015–0.15	Pb 0.03	8.77	HSM copper, similar to C19200, strip or welded tube, hard-temper tensile strength of 450 MPa, electrical conductivity varies: 35% IACS (welding), 65% IACS (normal), 70% IACS (high condition)	electronic connectors and contacts, lead frames, cable shielding, gasketing
C19500	Cu 96.0 Fe 1.0–2.0 Sn 0.10–1.0 P 0.01–0.35 Co 0.30–1.3	Zn 0.20 Al 0.02 Pb 0.02	8.91	strescon, similar to C19200, electrical conductivity of 50% IACS with a hard-temper tensile strength of 590 MPa, excellent hot and cold workability	electrical springs, terminals, connectors

* Minimum, except for ranges.

Zinc is by far the most important alloying element in the copper alloys. Zinc is a deoxidizer, but when it is added in quantities of 5 % or less, *phosphorus* may also be added to ensure full deoxidation. As zinc content in copper is increased, the density, melting point, electrical and thermal conductivity, and the modulus of elasticity (Young's modulus) decrease, but the strength, hardness, and coefficient of expansion increase.

Figure 6 is a copper – zinc phase diagram that illustrates some of these effects. The effect of zinc content on the color of the alloy is also of importance commercially, because many brasses are used for decorative purposes. The red copper color predominates to alloy C22600 (12.5 wt % Zn), where a red-gold color, very close to that of 18-carat gold, is evident. The color then progresses toward a yellow gold on to brass yellow. In the range of 38 wt % Zn, a buff red color appears, especially on the fracture surface. The buff red is a result of the presence of the beta phase along with the alpha phase and is an indication that the beta phase is present.

The *alpha phase* has good hot-working characteristics, but at the higher zinc content, the hot-working temperature range narrows perceptibly. With the *beta phase* present in the very high-zinc brasses, hot working improves. The alpha phase brasses have good cold-working properties, and C26000 exhibits the best cold-working properties, especially in deep drawing, of any of the copper alloys. When the beta phase is present in the very high-zinc brasses, cold working is hindered because the beta phase has poor cold-working characteristics. Richer zinc alloys are hot worked to a thickness at which additional hot working is no longer practical. The hot-worked surface is removed by milling, and the metal is subjected to a 2-h homogenizing anneal. This causes diffusion of the zinc, transforming the beta phase into alpha phase: good cold-working properties are then available.

There are few other elements alloyed with the brasses in the C20000 system. Phosphorus is one. When the metal is subjected to a hot water environment, 0.02 – 0.08 wt % As may be added to inhibit dezincification (C26310). One alloy (C23030) has 0.20 – 0.40 wt % silicon added for additional strengthening and resistance welding.

Since the production of the brass alloys relies predominantly on recycling scrap, impurities must be controlled carefully. Impurities encountered in the brasses affect processing of the metal more than they affect uses.

When lead approaches 0.025 wt %, the hot-working characteristics become impaired. Even

though industry standards permit 2 – 3 times that quantity, the lead must be controlled by the brass mills to the lower level.

Figure 6. The copper–zinc phase diagram [26]
The thermal conductivity of the alloys is given as a percentage of that of copper. Density, electrical conductivity, and thermal conductivity are for 20 °C.

Iron is a grain refiner. An annealing cycle may be set with the expectation of a specific quantity of iron being present. When the alloy being processed is low in iron (0.01 wt % Fe), the resulting annealed grain sizes may be too large, exceeding the specification. When the alloy being processed is high in iron (0.025 wt % Fe), the resulting grain sizes may be too small. Reannealing the high-iron metal at a higher temperature frequently results in *critical grain growth,* and the resulting grain size greatly exceeds the specification. Commercial standards permit 0.05 % Fe generally, but internal controls must be much tighter.

Phosphorus impurity levels must be restricted. If no iron were present, phosphorus would be a small problem, but iron is almost always present. Phosphorus contents > 0.001 % can lead to hot rolling problems and, even more definitely, loss of grain growth in annealing. With phosphorus present in the alloy along with iron, the grain refinement is extreme, making anneals unpredictable. Normally silver is counted as copper, with little effect on the properties of brass. When the brass is used for decorative work or coinage, however, silver can be a problem, and silver-bearing copper scrap cannot be used in brass where a true brass color is required.

Normally nickel is not a problem in brass, except in conjunction with iron or iron and phosphorus. Then nickel in quantities < 0.05 wt % can act as an additional grain refiner, giving annealing problems in further processing. Nickel can also act like silver in changing the color of the brass.

Table 8 describes the more popular brass alloys.

4. Wrought Leaded Brasses

The wrought leaded brasses (C30000 series) are brasses to which lead is added. The main purpose of adding lead is for machinability. As the quantity of lead increases up to ca. 3 wt %, the machinability index increases to 100 FMB for free-machining brass (C36000), as shown in Figure 7.

Figure 7. The effect of lead content on the machinability rating for leaded brass alloys

Because of the lead content, most leaded brasses are not easily worked either hot or cold. The copper-rich leaded brasses are best cold-rolled. The high-zinc-content leaded brasses have a good-to-excellent hot workability. At hot-working temperatures, the alpha-phase crys-

Table 8. Wrought copper–zinc alloys (wrought brasses)

UNS (ISO) alloy	Alloying elements, wt%	Permissible impurities (max.), wt%	Density, g/cm^3	Description, properties	Uses
C21000 (CuZn5)	Cu 94.0–96.0 Zn remainder	Pb 0.03 Fe 0.05	8.86	gilding metal (95% Cu), copper-red color, electrical conductivity of 56% IACS, hard-temper tensile strength of 390 MPa	coins, medals, tokens, bullet jackets, emblems, jewelry, craft work
C22000 (CuZn10)	Cu 89.0–91.0 Zn remainder	Pb 0.05 Fe 0.05	8.80	commercial bronze (90% Cu), bronze color, electrical conductivity of 44% IACS, hard-temper tensile strength of 420 MPa	weather stripping, hardware, primer caps, cosmetic cases, craft work, waveguides
C22600	Cu 86.0–89.0 Zn remainder	Pb 0.05 Fe 0.05	8.78	jewelry bronze (87% Cu), red-gold color, electrical conductivity of 40% IACS, hard-temper tensile strength of 460 MPa	costume jewelry, architectural, chain, slide fasteners, cosmetic containers, coinage
C23000 (CuZn15)	Cu 84.0–86.0 Zn remainder	Pb 0.05 Fe 0.05	8.75	red brass (85% Cu), gold color, electrical conductivity of 37% IACS, hard-temper tensile strength of 480 MPa	weather stripping, electrical and electronic connectors and contacts, condenser and heat-exchanger tubes, flexible hose, coins, badges, cosmetic containers, jewelry, dials
C24000 (CuZn20)	Cu 78.5–81.5 Zn remainder	Pb 0.05 Fe 0.05	8.67	low brass (80% Cu), yellow-gold color, electrical conductivity of 32% IACS, hard-temper tensile strength of 510 MPa	coins, tokens, medallions, clock dials, bellows, flexible hose, battery cups
C26000 (CuZn30)	Cu 68.5–71.5 Zn remainder	Pb 0.07 Fe 0.05	8.53	cartridge brass (70% Cu), yellow color, electrical conductivity of 28% IACS, hard-temper tensile strength of 525 MPa, highly susceptible to stress corrosion cracking	automotive radiator cores, bead chain, lamp fixtures, socket shells, screw shells, eyelets, hinges, locksets, cartridge cases, pumps
C26130	Cu 68.5–71.5 As 0.02–0.08 Zn remainder	Pb 0.05 Fe 0.05	8.53	arsenical cartridge brass (70% Cu), properties essentially same as C26000; arsenic helps prevent dezincification in automotive radiator tubes	automotive radiator tubes
C26800 (CuZn33)	Cu 64.0–68.5 Zn remainder	Pb 0.15 Fe 0.05	8.48	yellow brass (66% Cu), greenish-yellow color, electrical conductivity of 27% IACS, hard-temper tensile strength of 510 MPa	automotive radiator cores, tanks, reflectors, lamp fixtures, bead chain springs, screws
C28000 (CuZn40)	Cu 59.0–63.0 Zn remainder	Pb 0.30 Fe 0.07	8.39	Muntz metal (60% Cu), golden color, electrical conductivity of 28% IACS, hard-drawn tensile strength of 590 MPa, poor cold-working properties but excellent hot-working properties, subject to stress corrosion cracking and dezincification	decorative products, heat exchangers, brazing rods, sometimes used to match C23000 in color

talline structure is transformed to the beta-phase crystalline structure. The beta phase absorbs the lead and permits hot work to be done. Those alloys whose compositions skirt the alpha – beta phase boundary show good hot workability when in the beta phase. The beta phase can then be transformed to the alpha phase by diffusion annealing for good cold workability. These are the methods most brass mills use to cast, hot work, and cold work leaded brass alloys economically.

The lead in leaded brasses improves machinability because it is present as small inclusions, causing the machined chip to break away freely. This reduces the friction against the cutting tool, so heat does not build up or cause rapid dulling of the tool. Heat is more readily dissipated, and lubrication can be more beneficial. There may also be some slight lubrication from the lead.

There is another action operating that enhances the machinability of the leaded brasses. When some beta phase is permitted to remain, machinability increases. These beta particles retard cold workability, increasing fracturing tendencies. The beta fractures at the tool – metal interface, producing essentially the same effect as lead.

Lead and zinc are not the only two elements alloyed in the C30000 series. As in the C20000 series, several elements are added for special purposes:

Phosphorus is alloyed in the copper-rich leaded brasses to obtain additional deoxidizing for added strength and to inhibit dezincification. Nickel is added at times as a strengthener. Arsenic (up to 0.25 wt %) is added to help inhibit dezincification of the alloy, especially in water service. Antimony may be added to the leaded brasses for dezincification resistance. Quantities up to 0.10 wt % are used.

Aluminum is added to architectural bronze (C38000) to increase the resistance to atmospheric corrosion of the metal. Small quantities (< 0.6 wt %) are added to help develop aluminas (aluminum oxides) at the metal surface to aid in protection from the corrosive effect of the environment.

The effect of impurities in the leaded brasses is about the same as in the wrought brasses (C20000 series). The one major element that can give trouble is iron. As in the unleaded brasses, iron must be controlled carefully because of its effect on the recrystallization temperature of the alloys. Iron is also an effective grain refiner in the C30000 series. Table 9 contains information on the leaded brass alloys.

5. Wrought Tin Brasses

The copper – zinc – tin alloys (C40000 series), more commonly called the tin brasses, are probably the most underutilized alloys in the copper alloy families. In these alloys, both tin and zinc have been added to copper to produce alloys that in some compositions are stronger, have higher fatigue strength, better corrosion resistance, and better stress corrosion resistance than the high-zinc brasses. They are more economical than the phosphor bronzes (C50000 series) that are frequently used when these properties are needed.

Figure 8 illustrates this relationship on the basis of tensile strength. The strength of some C40000 series alloys is plotted against the sum of tin plus zinc alloyed. The strength of the C50000 series is plotted against the quantity of tin contained, and the strength of the C20000 series is plotted against the zinc contained.

Figure 8. Effect of alloying elements on the hard-temper tensile strength of the alloy series C50000, C40000, and C20000

The C40000 series found ready use during and after World War II as a substitute for the phosphor bronze alloys (C50000 series). Tin was difficult to obtain and costly, so the tin – zinc combination was acceptable as a substitute for the high-tin alloys, although some strength was sacrificed to obtain equal formability.

Table 9. Wrought copper – zinc – lead alloys (wrought leaded brasses)

UNS (ISO) alloy	Alloying elements, wt%	Permissible impurities (max.), wt%	Density, g/cm³	Description, properties	Uses
C31400	Cu 87.5–90.5 Pb 1.3–2.5 Zn remainder	Fe 0.10 Ni 0.7	8.83	leaded commercial bronze, rich bronze color, electrical conductivity of 42% IACS, normally supplied as rod and wire, machinability of 80%	screw machine parts, electrical plug-type connectors, builders hardware, screws, nuts, bolts
C33000	Cu 65.0–68.0 Pb 0.25–0.7 Zn remainder	Fe 0.07	8.50	low-leaded brass tubing, yellow color, electrical conductivity of 26% IACS, machinability of 60%	where degree of machinability and cold-working properties required: pump lines, T-bends, trap lines
C33200	Cu 65.0–68.0 Pb 1.5–2.5 Zn remainder	Fe 0.07		high-leaded brass tubing, yellow color, electrical conductivity of 26% IACS, machinability of 80%	same as C33000 except greater machinability
C33500 (CuZn35-Pb)	Cu 62.0–65.0 Pb 0.25–0.7 Zn remainder	Fe 0.15	8.47	low-leaded brass, yellow color, electrical conductivity of 26% IACS, machinability of 60%	clock parts, hinges
C34000 (CuZn35-Pb2)	Cu 62.0–65.0 Pb 0.8–1.5 Zn remainder	Fe 0.15	8.47	medium-leaded brass (64.5% Cu), yellow color, electrical conductivity of 26% IACS, supplied as bar, strip, rod, and wire, machinability of 60%	engravings, gears, nuts, bolts, knurled and threaded parts
C34200 (CuZn34-Pb2)	Cu 62.0–65.0 Pb 1.5–2.5 Zn remainder	Fe 0.15	8.5	high-leaded brass (64.5 Cu), grayish-yellow color, electrical conductivity of 26% IACS, supplied as bar, strip, rod, and wire, machinability of 90%	keys, clock parts, valve stems, general screw machine parts that also require cold working such as knurling and staking
C35000 (CuZn37-Pb1)	Cu 60.0–63.0 Pb 0.8–2.0 Zn remainder	Fe 0.15	8.47	medium-leaded brass (62% Cu), yellow color, electrical conductivity of 26% IACS, supplied as bar, strip, rod, and wire, machinability of 70%	clock parts, engravings, hinges, hose couplings, keys, zinc strainers, locks, washers
C36000 (CuZn36-Pb3)	Cu 60.0–63.0 Pb 2.5–3.7 Zn remainder	Fe 0.35		free-cutting brass, grayish-yellow color, electrical conductivity of 26% IACS, supplied as bar, rod, and wire, poor cold workability but fair hot workability, machinability of 100%	hardware parts, gears, pinions, high-speed screw-machining components

Resistance to stress relaxation has become an important property for many electrical and electronic connectors, which are frequently required to function while stressed at elevated temperatures. Examples are those found in computers and in the engine compartments of automobiles. Under such conditions, the spring member of a connector pair tends to relax, and a poor electrical connection results. The brasses, adequate for many room-temperature uses, may lose contact force at moderately high temperatures. The tin brasses have somewhat better resistance to stress relaxation than the brasses at temperatures up to 75 °C. (The phosphor bronzes have better resistance than the tin brasses.)

In choosing among these alloys for a particular use, strength, formability, stress relaxation resistance, and cost effectiveness all are factors that need to be considered. One of the stronger alloys, such as C42500, might be just as suitable as the higher cost phosphor bronzes. Full testing

of prototype parts under working conditions is always recommended.

The wrought tin brasses (C40000 series) can be subgrouped by the products or the forms in which these alloys are supplied and, consequently, how products are applied in their ultimate use:

1) Alloys C40000 – C43600, supplied most frequently in sheet and strip form, with minor quantities in rod, wire, and tube
2) Alloys C44300 – C49080, supplied most frequently in bar, rod, wire, or tube, with minor quantities in sheet and plate

In the alloys C40000 – C43600, tin contents range from 0.25 – 3.0 wt %. Zinc contents range from 4 – 11.5 wt %. No other elements are added to these alloys except in C42100, which contains 0.35 wt % Mn. Manganese is a deoxidizer, is a very moderate strengthener, increases electrical resistance, and might be beneficial for welding. Tin is a potent strengthener when it is added to copper. Zinc is also a good strengthener, but considerably higher quantities of zinc are needed to provide the equivalent of the strengthening provided by tin.

One of the important characteristics of these alloys is that their susceptibility to stress corrosion cracking is quite low. In applications in which the strength of a high-zinc brass is needed, but in which applied stresses would make the part subject to stress corrosion failure, an alloy like C42200 or C42500 can be used, and stress corrosion failure is most unlikely.

In the alloys C44300 – C49080, several elements are added to the copper – tin – zinc system for special purposes, depending on fabricating methods and ultimate use of the product. Several alloys have up to 0.25 wt % As, 0.10 wt % Sb, or 0.10 wt % P added to minimize dezincification. Alloys C47600 – C48600 have up to 2.5 wt % lead added for machinability. Small amounts of manganese (0.1 wt %) may be added to improve the hardness, or nickel (0.3 wt %) may be added for higher strength or corrosion resistance.

Table 10 describes the most widely used tin brasses.

6. Wrought Tin Bronzes and Brazing Alloys

In general, the wrought tin bronzes (C50000 series) provide the best combination of strength, electrical conductivity, and resistance to corrosion, as well as great versatility. The wrought tin bronzes can be classified into three subgroups:

1) Alloys containing copper, tin, and phosphorus (C50100 – C52400) usually produced as strip, rod, or wire (small amounts of other elements possibly present)
2) Leaded bronzes (C53200 – C54800) available in plate, sheet, strip, rod, wire, or bar
3) Copper – phosphorus and copper – silver – phosphorus alloys (C55180 – C55284) produced mainly as rod or wire products

6.1. Phosphor Bronzes

The term phosphor bronze usually refers to the alloys C50100 – C52400. The name phosphor bronze might imply a high phosphorus content, but these are copper – tin alloys that contain 0.01 – 0.35 wt % P for deoxidation.

The tin content is of paramount importance in this group of alloys. Figure 4 shows that additions of tin to copper reduce the electrical conductivity substantially. The maximum amount of tin that can be tolerated in wrought alloys is 10 wt % (Fig. 9). Above 10 wt %, as the copper – tin phase diagram indicates, a second phase is formed. This second phase is brittle and can be neither hot-worked nor cold-worked. In practice, alloys containing 5 wt % Sn cannot be hot-worked readily.

Tin is a low-melting-temperature element, and the temperature range between liquidus and solidus is quite large. During the solidification of castings, tin-rich molten metal solidifies last. Capillary action through the dendritic structure and pressures exerted by the solidifying copper-rich metal push the low-melting tin-rich liquid to the casting surface. This is called *inverse segregation.* (Segregation created through solidification is usually near the center of the cast bar.) A gray *delta surface* results, which is quite brittle and must be removed prior to working.

When inverse segregation takes place, the tin content in the interior of the casting is reduced

Table 10. Wrought copper–zinc–tin alloys (wrought tin brasses)

UNS (ISO) alloy	Alloying elements, wt%	Permissible impurities (max.), wt%	Density, g/cm^3	Description, properties	Uses
C40500	Cu 94.0–96.0 Sn 0.7–1.3 Zn remainder	Pb 0.05 Fe 0.05	8.83	high-conductivity bronze, electrical conductivity of 41% IACS, hard-temper tensile strength of 440 MPa	electrical meter clips, terminals, fuse clips, contact springs, washers
C41100	Cu 89.0–92.0 Sn 0.30–0.7 Zn remainder	Pb 0.10 Fe 0.05	8.80	lubaloy, electrical conductivity of 32% IACS, hard-temper tensile strength of 460 MPa	bushings, electrical conductors, thrust washers, flexible metal hoses, bearing sleeves
C42200	Cu 86.0–89.0 Sn 0.8–1.4 Zn remainder	Pb 0.05 Fe 0.05	8.80	lubronze, electrical conductivity of 31% IACS, hard-temper tensile strength of 500 MPa	sash chains, electrical terminals, connectors, springs, washers, fuse clips
C42500	Cu 87.0–90.0 Sn 1.5–3.0 Zn remainder	Pb 0.05 Fe 0.05 P 0.35	8.78	lubaloy X, electrical conductivity of 28% IACS, hard-temper tensile strength of 520 MPa	electrical switch springs, terminals, connectors, contacts, fuse clips, pen clips, weather stripping
C44300 (CuZn28-Sn1)	Cu 70.0–73.0 Sn 0.8–1.2 As 0.02–0.06 Zn remainder	Pb 0.07 Fe 0.06	8.53	arsenical admiralty, electrical conductivity of 25% IACS, hard-temper tensile strength of 670 MPa	condenser tubes and plates, heat-exchanger tubing, ferrules, strainers
C46400 (CuZn38-Sn1)	Cu 59.0–62.0 Sn 0.50–1.0 Zn remainder	Pb 0.20 Fe 0.10	8.41	uninhibited naval brass, electrical conductivity of 26% IACS, quarter-hard-temper tensile strength of 480 MPa (hardest temper available), machinability of 30%	condenser plates, welding rods, marine hardware, balls, nuts, bolts
C46500	Cu 59.0–62.0 Sn 0.50–1.0 As 0.02–0.06 Zn remainder	Pb 0.20 Fe 0.10	8.41	arsenical naval brass, electrical and mechanical properties same as C46400	same as C46400 where protection to dezincification is warranted
C48200 (CuZn37-SnPb)	Cu 59.0–62.0 Pb 0.40–1.0 Sn 0.50–1.0 Zn remainder	Fe 0.10	8.44	medium-lead naval brass, electrical and mechanical properties same as C46400, machinability of 50%	same as C46400, especially where better machinability is required
C48500 (CuZn37-Pb25Sn)	Cu 59.0–62.0 Pb 1.3–2.2 Sn 0.50–1.0 Zn remainder	Fe 0.10	8.44	high-lead naval brass, electrical and mechanical properties same as C46400, machinability of 70%	same as C46400, especially where better machinability is required

and may not meet the minimum tin content. Inverse segregation is more prevalent in alloys containing > 5 wt % Sn, leading many manufacturers to cast such alloys continuously in thin slabs (12 mm or 0.5 in. thick). Continuous casting minimizes inverse segregation through rapid and uniform heat removal.

Figure 10 illustrates the effect of increasing the tin content in the copper – tin alloys. Figure 8 shows that increasing the tin content increases the ultimate tensile strength. In addition, the spring-temper fatigue strength increases. All of the mechanical properties, especially the fatigue strength, of alloy C51000 are increased as the tin and phosphorus are raised toward the maximum of the limits specified. However, hot rolling becomes more difficult. Therefore, when the alloy is to meet the most demanding standards, it is usually cast continuously in thin bars, rather than hot rolled, so the tin and phosphorus can be maintained toward the maxima of the specified ranges and the metal toward the mechanical property maxima needed for some uses. When the additional requirement of 20 % IACS minimum electrical conductivity is specified for

C51100, however, the tin and phosphorus contents must be held low.

Figure 9. Copper – tin phase diagram
Maximum commercially usable tin content is 10 %, as indicated.

Figure 10. Effect of tin in the C50000 series of alloys

The only other elements alloyed in the phosphor bronzes are either nickel (0.10 – 0.40 wt %) or iron (0.05 – 0.15 wt %) to give extra strength or to act as grain refiners. As in many other alloys, the primary impurity that can be a problem is iron. Iron, being the strong grain refiner that it is, must be controlled to avoid annealing problems. Table 11 describes the most popular phosphor bronzes.

6.2. Leaded Phosphor Bronzes

The alloys C53200 – C54800 are the leaded phosphor bronzes. These alloys are used primarily for bearings. Alloyed with copper, the content is ca. 4 wt % tin (3.5 – 6.0 wt % Sn), 4 wt % lead (0.8 – 6.0 wt % Pb), and 0.2 wt % phosphorus (0.1 – 0.5 wt % P). With this high lead content the metal cannot be hot-worked. The most popular alloy of this group is C54400, which contains, besides the tin and lead, about 4 wt % zinc (1.5 – 4.5 wt %). This "444" alloy has excellent wearing properties, is easily cold-worked, and is readily machined (80 FMB). The zinc increases the hardness. The lead is actually high enough to be a lubricant when the alloy is used as a bearing surface. Table 12 further describes alloy C54400.

6.3. Brazing Alloys

The alloys C55180 – C55284 are copper – phosphorus or copper–silver–phosphorus brazing alloys normally supplied in the form of wire, rolled preforms, or powder. These are specialty alloys, which fit a special niche in the copper alloy system.

The copper – phosphorus alloys (C55180 and C55181) contain 4.8 – 7.5 wt % P. The phosphorus is alloyed not only for deoxidation, but also to provide a low melting temperature and increase the fluidity. This helps the molten alloy flow between the mating surfaces during brazing.

The copper – silver – phosphorus alloys have a similar purpose. The phosphorus content ranges from 4.8 to 7.2 wt % and provides for deoxidation, low melting temperature, and fluidity. The silver content ranges from 1.8 to 15.5 wt %. As the silver content increases, the melting point of the alloy decreases (Fig. 11). This alloy system provides four alloys of different melting temperatures. The silver in the alloy establishes the melting temperature to be used for brazing. If two or more joints must be made in close proximity, but not at the same time, the first braze should be made with an alloy of higher melting

Table 11. Wrought copper–tin alloys (wrought phosphor bronzes)

UNS (ISO) alloy	Alloying elements, wt%	Permissible impurities (max.), wt%	Density, g/cm³	Description, properties	Uses
C50500 (CuSn2)	Sn 1.0–1.7 P 0.03–0.35 Cu remainder	Pb 0.05 Fe 0.10 Zn 0.30	8.89	phosphor bronze, 1.25% E: electrical conductivity of 48% IACS, hard-temper tensile strength of 440 MPa	electrical contacts, connectors, flexible hose, telephone contacts, lead frames
C51000 (CuSn4)	Sn 4.2–5.8 P 0.03–0.35 Cu remainder	Pb 0.05 Fe 0.10 Zn 0.30	8.86	phosphor bronze, 5% A: electrical conductivity of 15% IACS, hard-temper tensile strength of 560 MPa	bridge bearing plates, beater bars, bellows, bourdon tubing, electric and electronic contacts and connectors, springs, brushes, washers
C51100 (CuSn4)	Sn 3.5–4.9 P 0.03–0.35 Cu remainder	Pb 0.05 Fe 0.10 Zn 0.30	8.86	phosphor bronze, 4%: electrical conductivity of 20% IACS, hard-temper tensile strength of 550 MPa	electrical and electronic connectors and contacts, switches, springs

temperature than the second. Table 13 describes these brazing alloys.

Figure 11. Copper – silver phase diagram [29]

7. Wrought Specialty Alloys

The special alloys (C60000 series) have seen a major expansion by manufacturers seeking stronger alloys that have good forming properties and good conductivity. The series covers basically the copper – aluminum alloys (aluminum bronzes), the copper – silicon alloys (silicon bronzes), and miscellaneous copper – zinc alloys (special brasses).

The search for a "stainless brass" that had the architectural ability of stainless steel to form a protective oxide led to the specialty bronzes. The development of these alloys in the 1960s and 1970s did not produce a stainless brass, but did present some new high-strength alloys with good formability and good tarnish resistance. Many of these new alloys are used extensively in electrical and electronic spring connectors.

When aluminum- or silicon-bearing copper alloys are annealed in atmospheres containing oxygen, the resultant oxide film is quite tenacious and insoluble in the normal cleaning solutions used in most brass mills. Special cleaning solutions and abrasive techniques must be employed to remove these oxide films. When such alloys are soldered or welded, special fluxes are required to dissolve the oxides, thus permitting the solder to wet the metal.

The alloys are used extensively for their desirable attributes. The use of either aluminum or silicon as an alloying element decreases the density substantially below that for most of the copper alloys. Figure 12 illustrates the marked effect of alloying aluminum with copper on the density of the alloy.

Figure 12. Density of copper – aluminum alloys

Both aluminum and silicon are strengtheners. Alloys with high strength and excellent forming properties permit a fabricator to employ thinner metal without reducing the strength of the fabricated part. The lower density and the reduced thickness permit more pieces to be manufactured from a kilogram of these alloys than could be manufactured from a kilogram of conventional copper alloy.

The specialty copper alloys are subdivided into three categories: (1) copper – aluminum alloys (aluminum bronzes), (2) copper – silicon alloys (silicon bronzes), (3) miscellaneous copper – zinc alloys.

7.1. Copper–Aluminum Alloys (Aluminum Bronzes)

The copper-aluminum alloys (C60000 – C64500) contain between 2 and 15 wt % Al, possibly with other alloying elements. When

cold finished products are to be manufactured, the aluminum content is limited to 9 wt %. The alloy is then an alpha solid solution, which has good cold ductility and may be either coldor hot-worked. These alloys may be supplied as strip or sheet, as well as hot-worked forms.

Above 9 wt % Al, the beta phase is present, which inhibits cold-working but facilitates hot-working. As a result, most alloys containing $\geqq$ 9 wt % Al are supplied as rod, wire, or hot-forgings.

Some alloys that contain 8 – 9 wt % Al may require a special annealing processing to transform the beta phase to alpha to facilitate cold-working. This processing is similar to the diffusion anneal used for the high-zinc alloy.

In addition to copper and aluminum, these alloys may contain one or more other elements.

Aluminum bronze alloys may contain up to 4.5 wt % Fe. The iron enhances corrosion resistance and is a strong grain refiner both for cast grains and for the following anneals. Iron is also a strengthener, increasing both the cold-worked and annealed strengths. As the iron content increases, the magnetic permeability (the ability of the alloy to attract a magnet) increases. This can hinder the use of high-iron alloys in electronics, communications, computers, etc.

Aluminum bronze alloys may contain up to 2 wt % Sn. The addition of tin improves the protection from dealuminification due to oxidizing corrosion of salt water. Tin is also an additional strengthener.

Alloyed in aluminum bronzes up to a maximum of 6 wt %, nickel is used basically to prevent dealuminification, with the additional function of a stabilizer to help control the annealed properties. Manganese is usually alloyed up to 3.5 wt % in the aluminum bronzes, although one alloy may contain up to 14 wt % Mn (C63380). The manganese is a deoxidizer and a strengthener. The high-manganese aluminum bronze alloys (Heusler alloys) have special magnetic properties.

Additions of up to 3 wt % Si may be made to the aluminum bronzes and still maintain good fabricating qualities. Silicon, another element that increases the strength of the alloy, also improves the fluidity for casting and improves weldability. Additions of up to 0.35 wt % As may be made to the aluminum bronzes to improve the oxidation corrosion resistance to reduce dealuminification. Additions of up to 0.55 wt % Co are made to act as strengtheners and additional preventors of dealuminification due to saltwater corrosion.

The impurity levels generally are maintained closely, as are the alloying elements within their designated limits. In many cases, the ranges for the alloying elements may be more closely confined internally than the ranges officially stated in the literature, to aid in processing. Some consequences of exceeding the stated composition limits are as follows:

1) Exceeding the impurity limits of zinc, tin, lead, silicon, or phosphorus may cause cracking during hot-working (hot shortness) and cause problems during subsequent welding.
2) Exceeding the silicon content may cause machining difficulties later.
3) Exceeding the manganese limits may reduce the normal corrosion resistance.
4) Exceeding the aluminum content decreases ductility (leading to ductility cracking during fabrication) and corrosion resistance.

Table 14 discusses the major aluminum bronze alloys.

7.2. Copper – Silicon Alloys (Silicon Bronzes)

Silicon may be alloyed with copper up to 4 wt %, which is the limit for the alpha structure, to give the silicon bronzes (C64700 – C66100). Figure 13 is a partial copper – silicon phase diagram, which clearly illustrates this alloying limitation. Beyond this limit, the alloy has poor working qualities, exhibiting a brittleness due to the presence of the gamma phase. The addition of silicon rapidly increases the work hardening rate, but ductility in the annealed state is high. The addition of silicon decreases the density, the electrical conductivity, and the melting point of the alloys. One important attribute of silicon is that it improves the resistance to stress relaxation. The improved fluidity gives excellent welding qualities to the copper – silicon alloys.

In addition to copper and silicon, the silicon bronzes may contain other alloying elements.

Lead is added in small quantities ($\leqq$ 0.8 wt %) to help improve the machinability of the alloy. Zinc is added in a low-silicon alloy as a

Table 14. Wrought copper–aluminum alloys (wrought aluminum bronzes)

UNS (ISO) alloy	Alloying elements, wt%	Permissible impurities (max.), wt%	Density, g/cm³	Description, properties	Uses
C60600	Al 4.0–7.0 Cu remainder	Fe 0.50	8.17	aluminum bronze, 5%: grade A: electrical conductivity of 17% IACS, hard-temper tensile strength of 410 MPa, available as sheet, strip, and rolled bar	fasteners, deep drawn "gold" decorations and jewelry, parts for corrosion resistance
C61000 (CuAl8)	Al 6.0–8.5 Cu remainder	Pb 0.02 Fe 0.50 Zn 0.20 Si 0.10	7.78	aluminum bronze, 8%: electrical conductivity of 15% IACS, hard-temper tensile strength of 480 MPa, available as rod and wire	bolts, shafts, pump parts and tie rods, welded overlay on steel for wear properties
C61300 (CuAl7-Fe3Sn)	Fe 2.0–3.0 Sn 0.20–0.50 Al 6.0–7.5	Pb 0.01 Zn 0.10 Mn 0.20 Si 0.10 Ni 0.15 P 0.015 for welding also: Cr 0.05 Cd 0.05 Zr 0.05 Zn 0.05	7.95	aluminum bronze, 7%: electrical conductivity of 12% IACS, hard-temper tensile strength of 590 MPa, magnetic permeability of 1.16 μ	fasteners, tube sheets, welded tubes, heat-exchanger tubes, acid-resistant piping, water boxes, other corrosion-resistant vessels
C61400 (CuAl8-Fe3)	Fe 1.5–3.5 Al 6.0–8.0 Cu remainder	Pb 0.01 Zn 0.20 Mn 1.0 P 0.015	7.89	aluminum bronze, 7%: electrical conductivity of 14% IACS, hard-temper tensile strength of 610 MPa, magnetic permeability of 1.16 μ	same as C61300
C61500	Al 7.7–8.3 Ni + Co 1.8–2.2 Cu remainder	Pb 0.015	7.69	lusterloy, gold color, electrical conductivity of 12.6% IACS, hard-temper tensile strength of 860 MPa, available in strip	hardware, decorative metal trim, deep drawn shells, jewelry
C62300 (CuAl10-Fe3)	Fe 2.0–4.0 Al 8.5–10.0	Sn 0.6 Mn 0.50 Si 0.25 Ni + Co 1.0	7.64	aluminum bronze, 9%: electrical conductivity of 12% IACS, typical tensile strength of 610 MPa, available as bar and rod	bearings, bolts, nuts, bushings, gears, cams, pump rods
C62400	Fe 2.0–4.5 Al 10.0–11.5 Cu remainder	Sn 0.20 Mn 0.30 Si 0.25	7.45	aluminum bronze, 11%: electrical conductivity of 12% IACS, typical tensile strength of 655 MPa, magnetic permeability of 1.34 μ, available as rod and bar	gears, wear plates, nuts, bolts, drift pins
C63200 (CuAl9-FeNi4)	Fe 3.5–4.3 Al 8.7–9.5 Mn 1.2–2.0 Ni + Co 4.0–4.8*	Pb 0.02 Si 0.10	7.64	nickel aluminum bronze, electrical conductivity of 7% IACS, hard-temper tensile strength of 640–720 MPa, depending on heat treatment, magnetic permeability of 1.04 μ, available as rod, bar, and forgings	nuts, bolts, shafts, propellers, spark-resistant parts
C63800	Al 2.5–3.1 Si 1.5–2.1 Co 0.25–0.5 Cu remainder	Pb 0.05 Fe 0.20 Zn 0.8 Mn 0.10 Ni + Co 0.20	8.28	coronze, electrical conductivity of 10% IACS, hard-temper tensile strength of 830 MPa, available as strip and sheet	electronic connectors, switches, springs, contacts
C64400	Al 3.5–4.5 Si 0.8–1.3 Ni + Co 4.2–5.0 Cu remainder	Pb 0.03 Fe 0.05 Sn 0.10 Zn 0.20	8.03	C644, electrical conductivity of 15% IACS, hard-temper tensile strength after precipitation heat treatment of 950 MPa, available as strip and sheet	electronic connectors and contacts, switches, springs

* Ni content must exceed Fe content.

strengthener and (possibly) an additional deoxidizer. Tin additions are made to improve corrosion resistance and improve fatigue strength. The addition of manganese to an alloy improves the microstructure through grain refinement. Manganese also improves the welding quality. Nickel, especially in the low-silicon alloys, is a strengthener. (Cobalt in small quantities is difficult to separate from nickel during refining; thus cobalt is counted as nickel.) Chromium is added to aid in grain refinement throughout the processing. Chromium may increase the alloy's resistance to stress relaxation.

For the silicon bronzes, the elements singled out as impurities include lead, iron, tin, zinc, aluminum, manganese, and nickel, although in specific alloys, one or more of these elements may be an alloying element.

Table 15 describes the major silicon bronze alloys.

Figure 13. Copper – silicon phase diagram [30, p. 483]

7.3. Miscellaneous Copper – Zinc Alloys

More highly alloyed than the copper – zinc alloys described in Chapter 3, the alloys C66400 – C69999 include alloys with a variety of chemical compositions, mechanical and physical properties, and uses. Zinc is the most popular alloying element, and the strength imparted is generally directly proportional to the zinc content. The addition of three or more alloying elements may drastically change the properties of the alloy.

Addition of up to 3 wt % Pb, most frequently an impurity, sometimes improves machinability. Addition of up to 4 wt % Fe is quite often used as a grain refiner and as a strengthener for special products. Addition of up to 1.5 wt % Sn improves the strength of some alloys. The ductility in the annealed state also is improved by the tin. Addition of up to 2.3 wt % Ni helps to control in-process conditions and to increase strength.

Addition of up to 6 wt % Al imparts greater hardness (strengthener) and, in lower quantities, also imparts greater ductility. Except for three special-purpose alloys (C66900, C69900, and C69910), manganese is limited to 5 %. Several alloys in this series are listed as manganese brasses or manganese bronzes. Manganese is a strong deoxidizer, but it also adds strength to the alloys and is a grain refiner. The three special-purpose alloys (C66900, C69900, and C69910) were initially developed as brazing alloys and sound-deadening alloys, e.g., Incramute. However, production problems and other, more efficient products eliminated their market.

Addition of up to 4.5 wt % Si improves the work hardening rate and, thus, the strength. The resistance to stress relaxation is improved, and in addition, the resistance welding properties are greatly improved.

Where cobalt is added to a copper – zinc – aluminum alloy, it forms a fine precipitate that is an excellent strengthener. Cobalt is added in quantities up to 0.7 %. Small additions of up to 0.8 wt % As are added to this series of alloys because they contain zinc. The arsenic acts as a corrosion inhibitor to minimize dezincification.

Addition of up to 0.06 wt % P ensures total deoxidation, with some strengthening of the alloys. Phosphorus also inhibits dezincification, as does antimony.

Table 16 describes selected alloys.

8. Wrought Copper – Nickel Alloys

The last series of wrought copper alloys is the C70000 alloy series, which basically consists of

Table 15. Wrought copper–silicon alloys (wrought silicon bronzes)

UNS (ISO) alloy	Alloying elements, wt%	Permissible impurities (max.), wt%	Density, g/cm³	Description, properties	Uses
C65100 (CuSi1)	Si 0.8–2.0 Cu remainder	Pb 0.05 Fe 0.8 Zn 1.5 Mn 0.7	8.75	low-silicon bronze B, electrical conductivity of 12% IACS, hard-temper tensile strength of 655 MPa, available as rod, wire, and tubing	hardware, bolts, car screws, nuts, marine hardware, heat-exchanger tubes, welding rod, hydraulic pressure lines, rivets, U-bolts
C65400	Sn 1.2–1.9 Si 2.7–3.4 Cr 0.01–0.12 Cu remainder	Pb 0.05 Zn 0.50	8.55	ultronze, electrical conductivity of 7% IACS, hard-temper tensile strength of 790 MPa, available as sheet and strip, thermal treatment enhances resistance to stress relaxation	electronic contacts, springs, connectors
C65500 (SuSi3-Mn1)	Mn 0.50–1.3 Si 2.8–3.8 Cu remainder	Pb 0.05 Fe 0.8 Zn 1.5 Ni + Co 0.6	8.53	high-silicon bronze A, electrical conductivity of 7% IACS, hard-temper tensile strength of 650 MPa, available as strip, wire, rod, and tubing	hardware, bolts, burrs, clamps, hinges, nails, nuts, screws, bearing plates, bushings, aircraft hydraulic lines, chemical containers

Figure 14. Copper – nickel phase diagram [30, p. 475]

Figure 15. Strengthening of copper by alloying with nickel

the copper – nickel alloys, with other elements added for specific purposes. The alloy series is subdivided into two distinct groups:

1) Copper-nickel alloys (C70100 – C72900)
2) Copper – nickel – zinc alloys (the nickel silvers, C73200 – C79900)

Each of these groups may be divided further into two subgroups, as discussed later.

The copper – nickel equilibrium diagram, Figure 14, shows that the two elements are completely soluble in each other in both the liquid and the solid states. This permits the full range of copper – nickel (copper-rich) alloys and nickel – copper (nickel-rich) alloys.

The color of the copper – nickel alloys depends on the percentage of nickel in the alloy, ranging from the red of pure copper, through rose, to near-white as 30 wt % Ni is approached. If a color match between alloys is required, as

Table 16. Miscellaneous wrought copper–zinc alloys

UNS (ISO) alloy	Alloying elements, wt%	Permissible impurities (max.), wt%	Density, g/cm^3	Description, properties	Uses
C66400	Fe 1.3–1.7 Co 0.30–0.7 Fe + Co 1.8–2.3 Zn 11.0–12.0 Cu remainder	Pb 0.015 Sn 0.05 Ni 0.05 Al 0.05 Mn 0.05 Si 0.05 P 0.02 Ag 0.05	8.74	cobron, electrical conductivity of 30% IACS, hard-temper tensile strength of 610 MPa, available as strip and sheet	electronic contacts, switches, spring washers, fuse clips, connectors, terminals
C66700	Cu + Ag 68.5–71.5 Mn 0.8–1.5 Zn remainder	Pb 0.07 Fe 0.10	8.53	manganese brass, electrical conductivity of 17% IACS, hard-temper tensile strength of 540 MPa, available as strip, sheet, rod, and wire	resistance-weldable brass products
C67500 (CuZn39-AlFeMn)	Cu + Ag 57.0–60.0 Fe 0.8–2.0 Sn 0.50–1.5 Mn 0.05–0.50 Zn remainder	Pb 0.20 Al 0.25	8.36	manganese bronze A, electrical conductivity of 24% IACS, half-hard-temper tensile strength of 410 MPa, available as rod and hot forged parts	automotive clutch disks, pump rods, shafting, pump balls, valve stems and bodies
C68700 (CuZn20-Al2As)	Cu + Ag 76.0–79.0 Al 1.8–2.5 As 0.02–0.06 Zn remainder	Pb 0.07 Fe 0.06	8.33	arsenical aluminum brass, electrical conductivity of 23% IACS, soft-temper tensile strength of 410 MPa, available as soft tubing	condenser, evaporator, and heat-exchanger tubes, especially for salt water
C68800	Zn 21.3–24.1 Al 3.0–3.8 Co 0.25–0.55 Al + Zn 25.1–27.1 Cu + Ag remainder	Pb 0.05 Fe 0.20	8.20	alcoloy, electrical conductivity of 18% IACS, hard-temper tensile strength of 780 MPa or 750 MPa (resistant to stress relaxation), available as strip	springs, switches, electrical and electronic contacts, relays, connectors, plug recepticals
C69000	Cu + Ag 72.0–74.5 Ni + Co 0.50–0.8 Al 3.0–3.8 Zn + Al 25.1–27.1 Zn remainder	Pb 0.025 Fe 0.05	8.20	high-strength copper alloy, electrical conductivity of 18% IACS, hard-temper tensile strength of 780 MPa, available as strip	same as C68800
C69400	Cu + Ag 80.0–83.0 Si 3.5–4.5 Zn remainder	Pb 0.30 Fe 0.20	8.19	silicon red brass, electrical conductivity of 6.2% IACS, 1/8th-hard-temper tensile strength of 690 MPa, available as rod and forged parts	corrosion-resistant valve stems, forged or screw machined parts
C69910	Fe 1.0–1.4 Zn 3.0–5.0 Al 0.25–0.8 Mn 28.0–32.0 Cu + Ag remainder	Pb 0.01	7.7	cobraze, rolled-temper tensile strength of 690 MPa, available in strip (< 1 mm thick)	brazing alloy with good wetability and antigravity flow

in souvenir coinage, the alloy makeup must be carefully controlled.

The 30 wt% Ni of alloy C71500 represents the present maximum nickel content in most copper alloy plants because the high processing temperatures during casting and hot-rolling are generally the maximum operating temperatures in the plants.

As nickel is alloyed to copper in increasing quantities, the tensile strength generally increases. The percent elongation decreases initially, but levels off. These effects are illustrated in Figure 15. Therefore, the strength of the alloy is increased with little loss in ductility, as measured by the percent elongation. However, this relationship is not generally observed in commercial products, since few pure copper–

nickel alloys are used. Usually one or more other elements are alloyed with the copper – nickel, which drastically changes this relationship.

8.1. Cupronickels

The copper – nickel alloys can be further subdivided into two subgroups:

1) Alloys C70100 – C71700, the major additional elements being iron and manganese, with minor amounts of other elements
2) Alloys C71900 – C72900, the other alloying elements becoming more and more effective, generating alloys that have little resemblance to the first group

The alloys C70100 – C71700 are primarily copper – nickel alloys to which iron and/or manganese are added.

Iron is an important element in the copper – nickel alloy system. Addition of up to 2.3 wt % Fe increases the strength with little loss in ductility. Iron also greatly improves the corrosion resistance of the alloys. Where the copper – nickel alloys have been used in saltwater environments without the iron addition, the copper – nickel products rapidly corrode by pitting. Replacement by alloys with the same copper : nickel ratio, but with 1.4 wt % Fe, allowed the product to last for years.

Thermal treatments should be used to ensure that the iron is in solution in the microstructure, especially in alloys C70600 and C71500. Initially, the iron must be placed in solution, and this can be done during the hot-working stage. Subsequently, all annealing operations must be followed by a cold-water quench to ensure that the iron stays in solution. If the iron does precipitate, the corrosion resistance and formability are seriously diminished.

Up to a maximum of 2.5 wt % Mn is added as a deoxidizer and a strengthener. Beryllium is added to one alloy (C71700) to generate a high-strength copper – nickel –beryllium alloy.

In addition, a new alloy (C70320) has been developed, containing no iron or manganese but which has up to 1.2 wt % Al, 1.2 wt % Si, and 0.50 wt % Cr. These elements are strengtheners and deoxidizers, but no published data are presently available to reveal the effects of this interesting combination of elements.

The major copper – nickel alloys in this subgroup are described in Table 17.

The alloys C71900 – C72900 contain some of the most interesting alloys presently available from the copper – nickel system. Several of the alloys are hardened through a spinodal-decomposition hardening mechanism. Spinodal structures may be developed in alloy systems that have a miscibility gap, with one phase separating out of the other during cooling in the gap. The spinodal structure is formed when an alloy in the system (in this case, the copper – nickel – tin system) is heated to a temperature above the miscibility gap, held at that temperature long enough for the metal to reach equilibrium, then rapidly quenched to a temperature within the gap, and held at that temperature long enough for the spinodal decomposition to reach completion.

The spinodal structure, in this case, is attributed to the uniform dispersion of tin-rich regions in the copper-rich matrix. The structure consists of an ordered, three-dimensional array of the tin-rich crystals. Under the high magnification of the electron microscope, the homogenized structure appears as a tweed or tightly woven cloth. Some spinodal-decomposition alloys have been manufactured for commercial use, but little has been published on their properties. The only spinodal alloy now available is C72900. Other alloys in this subgroup are also described in Table 18.

8.2. Copper – Nickel – Zinc Alloys

The alloys commonly called *nickel silvers* were formerly called *German silver.* They contain no silver except as a possible impurity. The history of German silver goes back to the time when the middle classes in Europe were first forming. They wanted eating utensils (table flatware and hollowware) that had the appearance of the silver pieces used by the rich, but at a lower price. These alloys were developed in Germany to meet this need; hence, the term German silver arose.

The copper – nickel – zinc alloys are strong and ductile; therefore, they have many uses. This group may be further divided into two subgroups:

Table 17. Wrought copper–nickel alloys

UNS (ISO) alloy	Alloying elements, wt%	Permissible impurities (max.), wt%	Density, g/cm^3	Description, properties	Uses
C70400 (CuNi5-Fe1Mn)	Fe 1.3–1.7 Ni + Co 4.8–6.2 Mn 0.30–0.8 Cu + Ag remainder	Pb 0.05 Zn 1.0	8.94	copper nickel, 5%: silver-rose color, electrical conductivity of 14% IACS, hard-temper tensile strength of 440 MPa, corrosion resistant, cheaper but less corrosion resistant than C70600, available as strip and tube	condensers, evaporator and heat-exchanger tubes, plates, ferrules
C70600 (CuNi10-Fe1Mn)	Fe 1.0–1.8 Ni + Co 9.0–11.0 Cu + Ag remainder	Mn 1.0 Zn 1.0 Pb 0.05	8.94	copper nickel, 10%: silver-pink color, electrical conductivity of 9% IACS, hard-temper tensile strength of 520 MPa, exceptionally resistant to seawater, available as strip and tube	condenser, distiller tubes, evaporators and heat exchangers, ferrules, seawater boat hulls
C71000 (CuNi20-Mn1Fe)	Ni + Co 19.0–23.0 Cu + Ag remainder	Pb 0.05 Fe 1.0 Zn 1.0 Mn 1.0	8.94	copper nickel, 20%: pale silver color; electrical conductivity of 6.5% IACS, hard-temper tensile strength of 520 MPa, available as strip and tube	communication relays, electrical springs, condenser plates, automotive oil coolers, ferrules, resistors
C71300 (CuNi25)	Ni + Co 23.5–26.5 Cu + Ag remainder	Pb 0.05 Fe 0.20 Zn 1.0 Mn 1.0	8.94	copper nickel, 25%: gray-silver color, electrical conductivity of 6% IACS, hard-temper tensile strength of 530 MPa, available as strip	U.S. coinage: the five-cent piece (the nickel) and the surface of the ten-cent through one-dollar coins
C71500 (Cu-Ni-30-Mn1Fe)	Fe 0.40–1.0 Ni + Co 29.0–33.0 Cu + Ag remainder	Pb 0.05 Zn 1.0 Mn 1.0	8.94	copper nickel, 30%: gray-white color, electrical conductivity of 4.6% IACS, hard-temper tensile strength of 565 MPa, should be annealed before soldering, available as plate, strip, rod, and tube	condensers, evaporators, distiller tubes, ferrules, saltwater pipes, and other saltwater uses

1) Alloys C73200–C77600 (except C76300 and C76390, which contain lead and other alloying elements and, thus, are grouped below) are nonleaded copper–nickel–zinc alloys.
2) Alloys C78200–C79900 are copper–nickel– zinc alloys that also contain lead and additional alloying elements.

The *copper–nickel–zinc alloys* increase in strength as the nickel and zinc additions increase. Figure 16 shows this: At hard temper the tensile strength increases, while the relative elongation remains steady. The plot of the difference between the yield strength and the tensile strength, ΔS, against this combination shows that ΔS follows the tensile strength, indicating that the higher strength does not diminish the formability.

These alloys generally exhibit good corrosion resistance, but they are somewhat susceptible to stress corrosion cracking. There are a few additional elements alloyed.

Up to 0.35 wt % Mn is added in two of the alloys for deoxidation. Manganese may be added many times, but in quantities below the permitted impurity level, as a precaution and aid in deoxidation. Up to 0.25 wt % Si is added at times to improve casting fluidity and strength.

These alloys are described in Table 19.

The *leaded copper–nickel–zinc alloys* have a specific quantity of lead added to improve the machinability of the alloy.

These alloys were used extensively for the manufacture of keys, especially automotive ignition and door keys. The strength and the wearing properties of the keys made from these alloys were superior and permitted long use without

Table 18. Wrought copper–nickel and other element alloys

UNS (ISO) alloy	Alloying elements, wt%	Permissible impurities (max.), wt%	Density, g/cm^3	Description, properties	Uses
C71900	Ni + Co 28.0–33.0 Mn 0.20–1.0 Cr 2.2–3.0 Zr 0.02–0.35 Ti 0.01–0.20 Cu + Ag remainder	Pb 0.015 Fe 0.50 Zn 0.05 C 0.04 Si 0.25 S 0.015 P 0.02	8.85	copper nickel chromium bearing, electrical conductivity of 4.4% IACS in spinodally decomposed condition, tensile strength of 540 MPa, available in pipe and tube	heat exchangers, water boxes, ferrules
C72200	Fe 0.50–1.0 Ni + Co 15.0–18.0 Cr 0.30–0.7 Cu + Ag remainder	Pb 0.05 Zn 1.0 Mn 1.0 Si 0.03 Ti 0.03	8.94	copper nickel chromium bearing, electrical conductivity of 6.53% IACS, hard-temper tensile strength of 480 MPa, available in pipe and tube	heat exchangers, saltwater boxes
C72400	Ni + Co 11.0–15.0 Al 1.5–2.5 Mg 0.05–0.40 Cu + Ag remainder	Pb 0.05 Fe 0.10 Zn 0.50 Sn 0.05 Mn 1.0	8.59	copper nickel aluminum, electrical conductivity of 10% IACS; solution heat-treated tensile strength of 1000 MPa, available in strip	electrical and electronic contacts, connectors, springs
C72500	Ni + Co 8.5–10.5 Sn 1.8–2.8 Cu + Ag remainder	Pb 0.05 Fe 0.6 Zn 0.50 Mn 0.20	8.89	copper nickel tin bearing, electrical conductivity of 11% IACS, hard-temper tensile strength of 570 MPa, not spinodally decomposable but thermal treatment following finish rolling develops a hardening precipitate that improves formability; available in strip, rod, wire, and tube	electronic connectors and contacts, lead frames, switches, springs, sensing bellows
C72900	Ni + Co 14.5–15.5 Sn 7.5–8.5 Mn 0.05–0.30 Cu + Ag remainder	Pb 0.02 Fe 0.50 Zn 0.50 Nb 0.10 Mg 0.15	8.94	pfinodal, electrical conductivity of 8% IACS, tensile strength of 860 MPa (spinodally decomposed from hard temper), rolled by using powder-metallurgical techniques because a brittle, unremovable Ni–Sn segregate develops in the liquid state; available in strip	electronic connectors, contacts, springs

fear of the key breaking off in the lock. This resulted in the thought that a silver key was a sign of quality. However, these keys were partially replaced by less expensive keys made from nickel-plated leaded brass or aluminum. With the advent of color-anodized aluminum keys, the market was even more rapidly eroded. With the loss of this large market, the supply of alloy has shrunk to that required by a relatively small specialty market.

The alloys are expensive because they require special care in manufacturing. They cannot be hot-rolled, and they work harden rapidly, necessitating a greater number of anneals during processing.

Elements other than nickel and zinc may be added.

Lead may be added to improve the machinability of the alloy. The maximum quantity allowable is 3.5 wt %. Up to 2.5 wt % Mn may be added for deoxidation and as a strengthener. Up to 0.6 wt % Sn may be added to improve the strength of the alloy.

The most important alloy in this group is described in Table 20.

Table 19. Wrought copper–nickel–zinc alloys (wrought nickel silvers)

UNS (ISO) alloy	Alloying elements, wt%	Permissible impurities (max.), wt%	Density, g/cm³	Description, properties	Uses
C73500	Cu 70.5–73.5 Ni + Co 16.5–19.5 Zn remainder	Pb 0.10 Fe 0.25 Mn 0.50	8.83	nickel silver, 18%: electrical conductivity of 8% IACS, hard-temper tensile strength of 545 MPa, normally available as strip in soft condition for deep drawing	deep drawn shells requiring high strength and good corrosion resistance, e.g., ballpoint ink tubes
C74300	Cu 63.0–66.0 Ni + Co 7.0–9.0 Zn remainder	Pb 0.10 Fe 0.25 Mn 0.50	8.65	nickel silver, 8%: electrical conductivity of 10% IACS, hard-temper tensile strength of 640 MPa, available as strip	flatware and hollow-ware for silver plate
C74500 (CuNi10-Zn25)	Cu 63.5–66.5 Ni + Co 9.0–11.0 Zn remainder	Pb 0.10 Fe 0.25 Mn 0.50	8.69	nickel silver, 65–10: electrical conductivity of 9% IACS, hard-temper tensile strength of 590 MPa, available as strip, rod, bar, and wire	rivets, screws, slide fasteners, eyeglass frames, hollowware, nameplates
C75200 (CuNi18-Zn20)	Cu 63.5–66.5 Ni 16.5–19.5 Zn remainder	Pb 0.05 Fe 0.25 Mn 0.50	8.73	nickel silver, 65–18: electrical conductivity of 6% IACS, hard-temper tensile strength of 590 MPa, available as strip, rod, and wire	rivets, screws, flat-ware for silver plat-ing, truss wire, cam-era parts, eyeglasses, jewelry, etching stock, radio dial
C75400 (CuNi15-Zn21)	Cu 63.5–66.5 Ni + Co 14.0–16.0 Zn remainder	Pb 0.10 Fe 0.25 Mn 0.50	8.69	nickel silver 65–10: electrical conductivity of 7% IACS, hard-temper tensile strength of 590 MPa, available as strip, rod, and wire	camera parts, optical parts, etching stock, jewelry
C75700 (CuNi12-Zn24)	Cu 63.5–66.5 Ni + Co 11.0–13.0 Zn remainder	Pb 0.05 Fe 0.25 Mn 0.50	8.69	nickel silver, 65–12: electrical conductivity of 8% IACS, hard-temper tensile strength of 590 MPa, available as strip, bar, rod, and wire	same as C75400
C77000 (CuNi18-Zn21)	Cu 53.5–56.5 Ni + Co 16.5–19.5 Zn remainder	Pb 0.05 Fe 0.25 Mn 0.50	8.70	nickel silver, 55–18: electrical conductivity of 5.5% IACS, hard-temper tensile strength of 690 MPa, available as strip, rod, and wire	optical goods, springs, resistance wire

ΔS is the difference between the yield strength and the tensile strength

9. Casting Alloys

The C80000 and C90000 series of alloys constitute the copper alloys that are supplied as castings. When a product cannot be manufactured from wrought alloy, casting is the next choice. Castings are used generally because the desired configuration cannot be made economically from wrought material either by rolling, stamping, drawing, forming, extruding, or a combination of these metal-forming operations. These cast alloys differ from the wrought alloys in several respects.

1) The cast alloys are not worked easily, either hot or cold; therefore, casting must be near final shape except for simple machining.
2) Although some of the same alloying elements are used in both the wrought and the cast alloys, alloying elements such as lead, tin, iron, and aluminum are generally present in greater amounts in castings than in wrought alloys. The alloying elements are added in casting alloys to improve the metal flow, the cast structure, or the strength. Some alloying elements cannot be used in wrought alloys because of the problems they would cause in processing and end use.
3) The impurity levels in casting alloys can be, and generally are, higher because the material is not worked.
4) The electrical conductivity of cast products is lower than that of wrought products because of the structure, even for pure copper.

In selecting an alloy for a part, many factors must be considered: strength, machinability, corrosion resistance, fatigue resistance, castability, metal cost, dimensions, tolerances, final cast, resistance to wear, lubricity in operation, etc.

9.1. Cast Coppers

The cast coppers C80000 – C81200 are used in the as-cast condition. They are not easily cast, usually having a narrow solidification range requiring extra risers to facilitate casting. At times, chills, insulating sleeves, and topping compounds help and may reduce the required risers.

Cast coppers are soft and easily deformed, especially when compared to higher alloyed casting alloys. Since they are castings, they must be machined to obtain the necessary fit. The low machinability ratings (e.g., 10 % FMB) make the cast coppers difficult to work with. Since the turnings are long, tough, and stringy, a chip breaker is helpful. Sulfur-free coolants should be employed to avoid contamination. If sulfurized oils must be used, parts must be cleaned immediately after machining to avoid staining.

Alloy C80500 contains at least 0.034 wt % Ag. None of the cast coppers can be heat treated to improve the hardness, but the addition of silver, as in the wrought copper alloys, contributes to a higher softening temperature and improved elevated-temperature properties. The alloy is easily soldered and brazed, but has limited weldability. Alloy C80500 generally corrodes like copper.

Alloy C81100 has about the same characteristics as C80500 except, lacking silver, it does not have the higher softening temperature and improved elevated-temperature properties.

Further information on these two cast coppers is found in Table 21.

Table 21. Cast coppers

UNS (ISO) alloy	Alloying elements (min.), wt %	Permissible impurities (max.), wt %	Density, g/cm³	Method of casting*	Description, properties	Uses
C80500	Cu + Ag 99.75 Ag 0.034	B 0.02	8.94	ABDEFG	boron-deoxidized copper, electrical conductivity of 91 % IACS, typical tensile strength of 170 MPa, machinability of 10 %	electrical and thermal conductors, heat sinks, corrosion- and oxidation-resistant uses
C81100	Cu + Ag 99.70	P + Si 0.01	8.94	ABDEFG	copper, electrical conductivity of 92 % IACS, typical tensile strength of 170 MPa, machinability of 10 %	electrical and thermal conductors, heat sinks, corrosion- and oxidation-resistant uses

* Methods of casting: A = centrifugal; B = continuous; C = die; D = investment; E = permanent mold; F = plaster; G = sand; H = other method.

9.2. High-Copper Alloys

The high-copper alloy castings, C81300 – C82900, generally contain ≧ 94 wt % Cu, with additions of beryllium or chromium to permit heat treating to improve the strength of the casting. The general characteristics of the alloys are the same as for the cast coppers, except that the higher alloying contents lower the thermal and electrical conductivities. As with the coppers, machining is difficult and requires special attention. Parts that may be solution annealed and aged are best machined after the solution anneal, with grinding after aging to obtain a proper fit. Care must be maintained during machining and grinding to avoid overheating the part even slightly; overheating can cause hard and/or soft spots to occur.

Alloy C81400 is a low beryllium – chromium copper alloy, and alloy C81500 is a chromium copper alloy. The latter has a much higher electrical – thermal conductivity, since beryllium drastically affects conductivity. Alloy C81500 is the more desirable alloy of the two.

Alloys C82000, C82200, C82500, and C82800 are coppers with varying contents of beryllium, cobalt, and nickel. As total alloying content increases, the strength of the casting increases. Alloys C82500 and C82800 have small additions of silicon that aid in castability, with some additional strengthening of the cast.

Further detailed information on the high-copper casting alloys is located in Table 22.

9.3. Copper – Tin – Zinc and Copper – Tin – Zinc – Lead Alloys

The C83000 – C85900 category of copper alloy castings is varied, covering a broad range of alloys. The lower numbered alloys have lower zinc contents. There are three subgroups: the "red brasses" (C83000 – C83900), the "semi-red brasses" (C84000 – C84900), and the "yellow brasses" (C85000 – C85900).

The alloys between C83000 and C83900 were formerly called red or leaded red brasses. These moderate-strength (240 MPa) alloys are mostly specialty alloys having specialized industrial applications (except for C83600 and C83800). They contain enough lead to greatly improve the machinability (34 % FMB for C83300 to 90 % FMB for C83800), which is important for making the casting useful.

The two most popular alloys, C83600 and C83800, are readily cast with normal quality casting procedures. Heavy cross sections up to 5 cm must be specially handled because of the wide solidification range – approximately 140 °C. A mushy layer forms during solidification and can result in micro or interdentritic shrinkage. However, special casting procedures can prevent this shrinkage. Alloy C83800 has somewhat lower mechanical properties, but its better machinability and lower cost sometimes favor it over C83600. Both alloys are readily joined by using soft soldering and brazing, although external stress should be avoided during brazing, for any stress may cause fractur-

Table 22. High-copper alloys – castings

UNS (ISO) alloy	Alloying elements*, wt%	Permissible impurities (max.), wt%	Density, g/cm³	Method of casting**	Description, properties	Uses
C81400	Cu 98.5 Be 0.02–0.10 Cr 0.6–1.0		8.81	ABDEFG	beryllium-modified chrome copper, electrical conductivity of 70% IACS, typical tensile strength of 365 MPa (heat treated); Be ensures Cr kept under control, allowing production of consistently high-quality chrome copper castings; machinability of 20%	electrical components meeting RWMA class II standards

* Minimum, except for ranges.
** Method of casting codes are explained in Table 21.

ing. These two alloys constitute the largest tonnage of copper casting alloys. Where corrosion resistance, leak tightness, and high operating temperatures are required, the tin bronze alloys (C90000 – C91900) are preferable.

The alloys between C84000 and C84900 were formerly called semi-red or leaded semi-red brass. The zinc content is greater, while the copper content is lower than for the first subgroup, but these alloys still have a red hue. Higher lead contents improve machinability.

The alloys also have a broad solidification range and the resultant shrinkage problems. In addition, these alloys tend to retain gas, leading to additional unsoundness. To control the gas and improve castability, small quantities of a deoxidizer (e.g., 15 wt % P – Cu) are added to the melt prior to casting. These alloys also suffer from hot shortness. Alloys C84400 and C84800 are the most popular alloys of this subgroup. Generally speaking, these alloys are low in price and readily worked.

The third subgroup of the copper – tin – zinc – lead alloys, C85000 and C85900, were formerly called the yellow and yellow leaded brasses because, having less copper and more zinc, the alloys take on the yellow hue of brass. These alloys are used extensively for die casting. This alloy subgroup is represented by C85200 and C85700. The high zinc content makes the metal cost less than the other C83000 – C85900 alloys. The two are readily cast. Gas absorption is insignificant because of the built-in protection of the evolving zinc vapors. However, the evolving zinc vapors must be rapidly oxidized; otherwise, the zinc severely corrodes the metallic structures, such as the casting dies, leading to a short die life.

When increased fluidity is desired to produce a smoother surface, up to 0.25 wt % Al can be added. All the alloys C83000 – C85900 may be readily nickel or chromium plated. Additional information on these three subgroups of alloys is found in Tables 23, 24, 25.

9.4. Copper – Manganese Alloys

The casting alloys C86000 – C86900 are sometimes called manganese or leaded manganese bronze alloys. Lead improves the machinability but a loss in strength may result when the lead content exceeds 0.1 wt %.

The chemical composition must be maintained during melting, especially the copper and zinc percentages. The foundry practice of "flaring," or heating the melt until zinc distills from the melt, resulting in the loss of zinc, changes the chemical composition and thus the mechanical properties of the casting, and should be avoided. Rather, the proper pouring temperature should be determined and maintained by better foundry practice.

The two most common alloys in this group are C86300 and C86500. The former has high tensile strength (760 MPa), while the latter has low tensile strength (450 MPa). Both have good corrosion resistance, especially to seawater. Alloy C86500 may be soldered or brazed with good results, but alloy C86300 does not lend itself to soldering or brazing because of the beta phase present, although it may be joined by using coated-metal arc welding. Stress relief annealing following joining is recommended for either alloy.

Further information on these two cast alloys is located in Table 26.

9.5. Copper – Zinc – Silicon Alloys

The casting alloys C87000 – C89900 are also called silicon bronze or silicon brass alloys. They have relatively high strength (average 600 MPa tensile strength) with good corrosion and wear resistance. The two alloys C87500 and C87800 have very similar chemical composition, but quite different applications.

Alloy C87500 is a general casting alloy, having excellent foundry properties. It has good machinability (50 % FMB) with moderately high strength (460 MPa). It has good weldability with both oxyacetylene and metallic arc methods, and has excellent soldering and brazing characteristics. Alloy C87500 is also highly resistant to dezincification under most corrosive environments.

Alloy C87800 is a die-casting alloy. Its chemical composition must be carefully controlled, especially with regard to impurities. It is a high melting point alloy – 870 °C – that requires cold-chamber die-casting machines at high pressures and lower speeds than either aluminum or zinc die-casting alloys. The high temperature contributes to die deterioration, a problem that die casters have overcome mainly with refined casting techniques. Joining the alloy can be a problem, since brazing is only fairly successful, while other methods are not recommended. Alloy C87800 has poor machinability (30 % FMB), but this is sufficient for its uses. The alloy is used where the greatest strength and the highest resistance to mechanical wear are needed in a die-cast part.

* For continuous casting, P = 1.5 wt% max.
** Method of casting codes are explained in Table 21.

Further information on these two casting alloys is found in Table 27.

9.6. Copper – Tin Alloys

The alloys C90000 – C91900 are commonly called tin bronzes. For some purposes they may have small quantities of zinc ($\leqq 5\,\%$), nickel ($\leqq 2\,\%$), or phosphorus ($\leqq 1.2\,\%$). In general, good foundry practices must be followed since the alloys have a wide solidification range (160 °C) requiring risers, chillers, and other practices to control shrinkage. Topping compounds and the use of a small quantity of phosphor copper as a deoxidizer aid in casting. Care must be taken in brazing the alloys because the brazing temperature is in the hot short range, and any stress applied to the casting during heating or cooling in this region can cause fracturing. The machinability of these alloys is relatively poor (20 – 30 FMB), requiring special attention.

There are three major alloys in this group. The first is C90500, which contains an addition of zinc to increase the strength and hardness of the alloy. The alloy is a moderately strong (320-MPa

Table 25. Yellow brass and leaded yellow brass casting alloys

tensile strength) general-purpose bronze casting alloy. It has many uses where there are severe working conditions under heavy pressure, as in bearings and gears.

The second alloy is C90700, which is a tin bronze that has been deoxidized with a trace of phosphorus. The alloy is known for its combination of good strength, ductility, and corrosion resistance. The alloy must be given additional attention during casting, because of shrinkage, and upon chilling, to reduce the grain growth that occurs upon slow cooling. The alloy has no lead, making machining difficult. The alloy is best mated to hardened steel. Machining accuracy is required so that both parts are properly mated. This alloy is especially useful in worm gears.

The third alloy is C91700, which contains, in addition to the copper and tin, a small quantity of nickel as a strengthener and a trace of phosphorus as a deoxidizer. This alloy also has a good combination of strength, ductility, and resistance to wear. Widely used for gears, it was called nickel gear bronze.

Further detailed information on these three casting alloys is found in Table 28.

9.7. Copper – Tin – Lead Alloys

The alloys C92000 – C94500 are essentially an extension of the copper – tin casting alloys, with additions of lead to improve machinability. These alloys have the same casting and joining characteristics as the copper – tin alloys (Sec-

tion9.6). Zinc, nickel, and phosphorus may be added.

These alloys may be placed into two subgroups. The first has low lead contents (C92000 – C92900), whereas the second has high lead contents (C93000 – C94500). The addition of lead slightly weakens the alloys, possibly by 25 MPa of this tensile strength, but the improved machinability is the driving force for their use.

Three low-leaded tin bronzes from the first subgroup are important. Alloy C92300 contains zinc as a strengthener. The alloy possesses a good combination of strength (275-MPa tensile), good corrosion resistance, and good machinability (42 % FMB). Alloy C92500 contains nickel as a strengthener and is deoxidized with phosphorus. Its characteristics are very similar to C90700 except the lead improves the machinability rating from 20 to 30 % FMB, thus enabling better mating with hardened steel. The strength remains essentially the same – 300 MPa tensile. Alloy C92900 has higher nickel and lead contents than C92500, with a correspondingly higher machinability rating of 40 % FMB.

The higher lead-containing tin bronze casting alloys are represented by four alloys. Alloy C93200 has zinc add for improved strength, hardness, and castability. The lead content improves the machinability rating to 70 % FMB and places the alloy in the area of having excellent anti-friction characteristics with excellent load capacity. Alloy C93500 has zinc and lead additions. The lead content is sufficient to place this alloy in the excellent anti-friction region, ideal for manufacturing bearings and bushings that operate below 230 °C. Alloy C93700 has no strengthening additions to its basic copper –tin– lead alloy makeup. The alloy has exceptionally high casting fluidity; therefore, special precautions must be taken when sand casting to minimize mold-sand penetration. The high machinability rating – 80 FMB – indicates the alloy is easily machined and has excellent anti-friction properties. Alloy C94500 is 19 wt % Pb, a very high lead content. Cast bearings and bushings made from this alloy have superior resistance to scoring and seizure, and exceed the endurance and danger limits of the regular bearing bronzes. Applications involve high speeds, poor lubrication, gritty environments, and heat generating loads at elevated temperatures. The lead is in globular form, thus permitting self-lubrication.

Further information about these alloys is detailed in Tables 29 and 30.

9.8. Copper – Tin – Nickel Alloys

The small group of copper – tin – nickel casting alloys (C94600 – C94900) forms a special niche in the casting alloys. Their use is limited to areas where heat treatment is used to obtain tensile strengths of 450 MPa. They have easy castability, low shrinkage, and a fine grain structure.

Alloy C94700 may contain a small amount of zinc to aid in strength and castability. In the tempered condition, nominal strengths of 450 MPa are reached, but the alloy has a machinability rating of only 30 % FMB. Alloy C94800 is essentially the same but with some lead for improved machinability (45 % FMB). The lead, however, reduces the tensile strength to 410 MPa.

Since heat treatment normally causes distortion, the higher machinability rating is important even with the reduction in the mechanical properties. Both alloys are difficult to weld, but they may be joined by silver or soft soldering.

Further details on these two alloys are located in Table 31.

9.9. Copper – Aluminum – Iron and Copper – Aluminum – Iron – Nickel Alloys

The C95000 – C95900 series of alloys is commonly referred to as the aluminum bronzes; these generally are high-strength alloys. The aluminum bronze alloys are sufficiently interesting to warrant consideration in most cases where a casting alloy is to be employed. Some of their high strength is available in the as-cast condition, and some is derived from heat treatment.

The three basic aluminum bronze alloys are C95300, C95500, and C95800. All have fairly high strength and hardness, excellent corrosion resistance, good wearing characteristics, good machinability, and good fatigue properties. Alloys C95300 and C95500 may be used to 400 °C, while C95800 is restricted to 370 °C.

Alloy C95300 is a heat-treatable casting alloy. When cast, the typical tensile strength is

Table 29. Copper – tin – lead casting alloys (leaded tin bronzes)

UNS (ISO) alloy	Alloying elements, wt %	Permissible impurities (max.), wt %	Density, g/cm³	Method of casting**	Description, properties	Uses

C92500 (CuSn12-Pb2)	Cu 85.0–88.0 Sn 10.0–12.0 Pb 1.0–1.5 Ni + Co 0.8–1.5	Zn 0.50 Fe 0.30 Sb 0.25 S 0.05 P 0.30* Al 0.005 Si 0.005		ABEG	leaded tin bronze, 82-11-1-0-1: typical tensile strength of 300 MPa, machinability of 30%	gears, automotive synchronizer gears and rings
C92900	Cu 82.0–86.0 Sn 9.0–11.0 Pb 2.0–3.2 Ni + Co 2.8–4.0	Zn 0.25 Fe 0.20 Sb 0.25 S 0.05 P 0.50* Al 0.005 Si 0.005	8.87	ABEG	leaded nickel–tin bronze, 84-10-2 1/2-0-3 1/2: electrical conductivity of 9.2% IACS, typical tensile strength of 320 MPa (permanent mold or sand cast), machinability of 40%	gears, wear plates, guides, cams

* For continuous casting, P = 1.5 wt%, max.
** Method of casting codes are explained in Table 21.

520 MPa. After heat treatment, this is raised to 590 MPa. Products from this alloy are 10% lighter than comparable products of tin bronze. Casting the alloy requires experience with careful control and special techniques to maintain sound castings. The alloy is readily joined by most welding, brazing, or soldering techniques.

Alloy C95500 is a heat-treatable casting alloy. In the cast state it typically exhibits a tensile strength of 690 MPa, but after heat treatment this is increased to 830 MPa. It also has a lower density than the tin bronzes. The alloy is more easily cast than C95300, but more care must be used when joining the alloy. The alloy is readily welded, but is rated only fair for brazing. Soldering and oxyacetylene welding are not recommended.

Alloy C95800 is not heat-treatable. A typical tensile strength in the cast state is 655 MPa. The slightly lower aluminum and higher nickel contents degrade the density advantage of the previous two alloys. As with alloy C95300, care must be taken during casting to develop sound castings. The alloy is suitable for joining by soldering and some welding techniques, but brazing is rated only as fair, while carbon arc or oxyacetylene welding should be avoided.

Further information is detailed in Table 32.

9.10. Copper – Nickel – Iron Alloys

The group C96000 – C96900 not only covers casting alloys containing copper, nickel, and iron but also those containing beryllium. The standard copper – nickel – iron alloy is C96400, which gives strong (470 MPa) and ductile castings having excellent corrosion resistance. The iron addition improves the corrosion and erosion resistance in seawater, making the alloy a preferred one for use on oceangoing ships. In addition, the alloy may be joined by brazing, soldering, or welding, except for oxyacetylene or carbon arc welding, which are not recommended.

The beryllium-containing alloys are an outgrowth of alloy C96400, with the beryllium present to permit heat treating. Alloys C96600 and C96700 show the same corrosion attributes of C96400, but after heat treatment, tensile

* For continuous casting, P = 1.5 wt % max.
** Method of casting codes are explained in Table 21.

strengths of 830 MPa and 860 MPa are obtainable. One basic recommendation is that the machining be carried out after the parts are completely heat treated to avoid problems with fit.

Further details on these alloys are given in Table 33.

9.11. Copper – Nickel – Zinc – Tin – Lead Alloys

These alloys C97000 – C98900 form a group that is used extensively for ornamental and decorative purposes where a white alloy is desired. The alloys are responsive to machining and exhibit good corrosion resistance, but they are not heat treatable to increase strength or hardness. The two alloys discussed from this group vary widely in chemical composition.

The first alloy is C97300. This alloy has good foundry characteristics, castings are readily machined (70 % FMB), and it may be joined using soldering and brazing methods. The high lead content precludes welding. The alloy is not a strong one, with a typical tensile strength of 240 MPa.

The second alloy is C97800. This alloy has only fair castability and fluidity, but with proper techniques and good foundry practices, excellent castings can be produced. The same joining procedures are used for this alloy as for C97300.

Table 31. Copper – tin cast alloys (tin bronzes)

UNS (ISO) alloy	Alloying elements, wt %	Permissible impurities (max.), wt %	Density, g/cm³	Method of casting*	Description, properties	Uses
C94700	Cu 85.0–90.0 Sn 4.5–6.0 Zn 1.0–2.5 Ni 4.5–6.0	Pb 0.10 Fe 0.25 Sb 0.15 Mn 0.20 S 0.05 P 0.05 Al 0.005 Si 0.005	8.87	ABDEG	constructional bronze; electrical conductivity of 20% IACS, typical tensile strength of 340 MPa (as cast), 450 MPa (tempered), and 590 MPa (heat treated), machinability of 25% FMB in tempered state, 30% FMB as cast	gears, cams, valves and valve stems, feeding mechanisms, roller guides, cylinders for presses, conveyer chains and general construction castings
C94800	Cu 84.0–89.0 Sn 4.5–6.0 Pb 0.30–1.0 Zn 1.0–2.5 Ni 4.5–6.0	Fe 0.25 Sb 0.15 Mn 0.20 S 0.05 P 0.05 Al 0.005 Si 0.005	8.87	EG	leaded nickel tin bronze, electrical conductivity of 14% IACS, typical tensile strength of 310 MPa (as cast) and 410 MPa (tempered), machinability of 45% FMB	essentially same as C94700 except where better machinability is required

* Method of casting codes are explained in Table 21.

Table 32. Copper–aluminum–iron and copper–aluminum–iron–nickel cast alloys (aluminum bronzes)

UNS (ISO) alloy	Alloying elements*, wt %	Permissible impurities (max.), wt %	Density, g/cm³	Method* of casting***	Description, properties	Uses
C95300	Fe 0.8–1.5 Al 9.0–11.0 Cu 86.0		7.53	ABEFG	aluminum bronze 9B, 89-1-10: electrical conductivity of 13% IACS, typical tensile strength of 520 MPa (as cast) or 590 MPa (heat treated), machinability of 55%	pickling baskets, nuts, gears, steel mill slippers, marine equipment, non-sparking hardware, welding jaws
C95500 (CuAl10-Fe5Ni5)	Fe 3.0–5.0 Ni 3.0–5.5 Al 10.0–11.5 Cu 78.0	Mn 3.5	7.53	ABEFG	aluminum bronze 9D, 81-4-4-11: electrical conductivity of 8.5% IACS, typical tensile strength of 690 MPa (as cast) or 830 MPa (heat treated), machinability of 50%	valve guides and seats in aircraft engines, corrosion-resistant parts, bushings, gears, worms, pickling hooks and baskets, agitators
C95800 (CuAl10-Fe5Ni5)	Fe 3.5–4.5** Ni 4.0–5.0 Al 8.5–9.5 Mn 0.8–1.5 Cu 79.0	Pb 0.05 Si 0.10 Sn 0.10	7.64	ABEFG	alpha nickel aluminum bronze, 81-5-4-9-1, propeller bronze: electrical conductivity of 7.1% IACS, typical tensile strength of 655 MPa, machinability of 50%	propeller blades and hubs for service in fresh and salt water, fittings, gears, worm wheels, valve guides and seals

* Minimum, except for ranges. ** Ni content must exceed Fe content.
*** Method of casting codes are explained in Table 21.

Table 33. Copper–nickel–iron cast alloys (copper nickels)

UNS (ISO) alloy	Alloying elements, wt %	Permissible impurities (max.), wt %	Density, g/cm^3	Method of casting*	Description, properties	Uses
C96400	Cu 65.0–69.0 Fe 0.25–1.5 Ni + Co 28.0–32.0 Nb 0.50–1.5	Pb 0.03 Mn 1.5 Si 0.50 C 0.15	8.94	ABG	70–30 copper nickel, electrical conductivity of 5% IACS, typical tensile strength of 470 MPa, machinability of 20%	valves, pump bodies, flanges, and elbows requiring resistance to seawater
C96600	Fe 0.8–1.1 Ni + Co 29.0–33.0 Be 0.40–0.7 Cu remainder	Pb 0.01 Mn 1.0 Si 0.15	8.80	ABDEG	beryllium cupronickel, electrical conductivity of 4.3% IACS, tensile strength of 830 MPa (heat treated), machinability of 40%	similar to C96400 except where greater strength is required, high-strength constructional parts for seawater, especially for long, unattended submergence, e.g., pump bodies, valve bodies, seawater line fittings
C96700	Be 1.1–1.2 Ni 29.0–33.0 Fe 0.7–1.0 Zr 0.10–0.20 Ti 0.10–0.20 Cu remainder	Mn 0.7 Si 0.15 Pb 0.1	8.60	ABDEG	modified beryllium cupronickel, electrical conductivity of 4.3% IACS, typical tensile strength of 560 MPa (as cast) or 860 MPa (heat treated), better castability than C96600, machinability of 40%	same as C96600, great use for plastic tooling

* Method of casting codes are explained in Table 21.

This alloy is somewhat stronger than C97300, with a typical tensile strength of 380 MPa.

Further detailed information is found in Table 34.

9.12. Special Cast Alloys

The alloys placed in the group C99000 –C99999 do not fit into any previous chemical classification. Each alloy has a special purpose; therefore, commercial usage is limited.

Alloy C99400 is noted for its resistance to dezincification and dealuminification. It is used in those environments where these types of corrosion are a problem or are expected to be a problem. It is somewhat heat treatable, the nominal as-cast tensile strength of 455 MPa being increased to 545 MPa. It has fair-to-good castability, but sometimes requires special foundry techniques.

Alloy C99700 is a low-cost white alloy used for ornamental and decorative purposes instead of C97800. The alloy has a good machinability rating (80 % FMB) and a strength comparable to C97800.

Further information is detailed in Table 35.

10. Master Alloys

Certain elements are to be added to the casting melt that are difficult to dissolve or that evolve as a fume, making exact additions difficult to attain. The use of master alloys aids in the introduction of these troublesome elements. A master alloy is rich in one or more addition elements in a matrix of the major element, in this case copper.

These master alloys may not be true alloys but may be simply mixtures of elements or their compounds. They are produced in various products or configurations:

1) *Pig.* This configuration usually is used where the element to be added is difficult to melt or dissolve. Adding iron to copper is an example. This master alloy is developed at much higher temperatures and times to reach solubilities that are not available in casting the basic alloy.
2) *Pellets.* Essentially the same product as pig, but cast in water to produce the pellets. The pellets dissolve more rapidly than the pig, thus giving more flexibility in the operation.

Table 34. Copper–nickel–zinc casting alloys (nickel silvers)

UNS (ISO) alloy	Alloying elements, wt %	Permissible impurities (max.), wt %	Density, g/cm³	Method of casting*	Description, properties	Uses

C97800	Cu 64.0–67.0 Sn 4.0–5.5 Pb 1.0–2.5 Zn 1.0–4.0 Ni + Co 24.0–27.0	Fe 1.5 Sb 0.20 S 0.08 P 0.05 Al 0.005 Mn 1.0 Si 0.15	8.86	ADEG	leaded nickel bronze, 66-5-2-2-25: electrical conductivity of 4.5% IACS, typical tensile strength of 380 MPa, machinability of 60%	ornamental castings, sanitary fittings, valve bodies, valve seats, musical instrument components

* Method of casting codes are explained in Table 21.

Table 35. Special casting alloys

UNS (ISO) alloy	Alloying elements, wt %	Permissible impurities (max.), wt %	Density, g/cm³	Method of casting**	Description, properties	Uses
C99400	Ni 1.0–3.5 Fe 1.0–3.0 Al 0.50–2.0 Si 0.50–2.0 Zn 0.50–5.0 Cu remainder	Pb 0.25 Mn 0.50	8.30	ABDG	nondezincification alloy, NDZ: electrical conductivity of 16.8% IACS, typical tensile strength of 455 MPa (as cast) or 540 MPa (heat treated), machinability of 50%	valve stems, propeller wheels, electrical parts, gears for mining, marine, or other equipment where resistance to dezincification or dealuminification is required
C99700	Cu 54.0* Ni 4.0–6.0 Al 0.50–3.0 Mn 11.0–15.0 Zn 19.0–25.0	Sn 1.0 Pb 2.0 Fe 1.0	8.19	ADEFG	white manganese brass, electrical conductivity of 3% IACS, typical tensile strength of 380 MPa, machinability of 80%	building hardware, architectural and ornamental fittings, marine hardware, floor drain covers, food handling equipment, swimming pool hardware

* Minimum.
** Method of casting codes are explained in Table 21.

3) *Chunks.* Similar to pig, chunks are not cast in a mold, but in thin friable slabs. The chunks may be added to the melt during charge preparation, added as a ladle addition, or at any convenient point. Adding ferromanganese or phosphorus copper master alloy are examples.
4) *Wire.* This form of a master alloy is quite special and is not an alloy at all. When producing this wire, a tube of the matrix is filled through special compaction of a powder containing a compound of the required element. The tube is then redrawn to a convenient diameter – e.g., 2 mm. The wire contains a known quantity of the element to be added. Adding zirconium to copper is an example using this technology. This method is used for elements that readily fume off the melt.
5) *Briquette.* This configuration readily permits the use of powders to produce the "master alloy." These powders may be pure elements or compounds of a desired element that are compacted. In many cases, the compounds being developed are not element additions, but flux added to purify the melt. This method is widespread in the casting industry, and a prime example is the casting of phosphor bronze alloys.

Generally the producers of master alloys are purchasers and sellers of scrap products. Many of the master alloys are developed at the request of individual customers, but most are made available on a commercial basis. The chemical content ranges are rather broad compared to those of wrought products.

11. Safety and EnvironmentalAspects

Several of the elements associated with copper alloys are toxic. Most are rendered harmless through the use of exhaust systems to remove gaseous effluents, with precipitators and filters to remove the solid particles. The exhaust system removes the fumes generated in melting and transports them rapidly to precipitators to remove the major solid material and then on to bag houses. This procedure removes and collects 99.9 % of the solids.

Usually where casting facilities are present and zinc is an alloying constituent, a thorough exhaust system is used to collect all fumes from the melting and casting area. In the past, workers became ill with "brass founders' ague," "brass chills," or "metal fume fever." Today these conditions do not normally exist.

These collection systems remove such potentially dangerous elements as cadmium, antimony, arsenic, lead, selenium, manganese, tellurium, titanium, and zinc. All of these elemental fumes are rapidly oxidized into removable solids.

Gaseous fumes developed during cleaning or pickling must be removed form the work area. Normally these may be exhausted to the atmosphere, where they are dissipated and rendered harmless. In areas where the general environment cannot tolerate the additional contamination, the fumes may pass through a wet (water spray) collector where a majority of the fumes is removed.

One effluent not always recognized is the metal powder or "dust" often generated in operations. Where any powder is generated, it itself represents an explosive hazard and should be removed from the area. Such products should be vacuumed away to a safe collecting area.

One element not mentioned above is *beryllium.* Beryllium can be highly toxic, not only in the producer's plant, but also in the ensuing user operations.

Grinding and polishing generate dust, but many users have not realized that stamping and forming operations may also form dust particles. Welding – spot, seam, or other types – will produce a fume. Even some soldering operations may produce a fume when soldering beryllium-containing alloys.

Any alloy containing beryllium requires special precautions and ventilation where parts are made by any means that could produce a dust or fume. Most manufacturers of products containing beryllium supply a precautionary note advising that inhalation of excessive concentrations of airborne beryllium can cause pulmonary or respiratory problems.

12. Economic Aspects

New alloys are being developed continuously to fill voids where existing alloys are found wanting. Even though most new alloys do not perform to expectations, the mass of trials does produce breakthroughs that extend the usage of copper alloys. The percentage of copper in alloys is dropping, on the average, but this is offset by expansion of the total copper market and counteracts some of the effect of substitution.

No longer do international borders form barriers to markets. Strip products now have better finishes, closer physical and mechanical tolerances, and better flatness than U.S. producers would have produced without worldwide competition. A new concept of quality control – quality assurance – has emerged to improve product quality through closer in-process inspection and broader use of computerization. The just-in-time delivery of high-quality products to the fabricator smooths out production schedules.

A pervasive change in the copper alloy market has been the continual miniaturization of the parts. One example is the automobile radiator. Brass metal for radiator tube has been reduced in thickness from 0.114 to 0.0064 mm, total usage dropping even more rapidly because radiators are smaller and have less surface area. The tanks and headers, also correspondingly smaller, have undergone a thickness reduction from 0.813 to 0.381 mm. (Also see → Copper, Chap. 7.3.)

One interesting outgrowth of miniaturization is a relatively new concept – shaped wire. The wire is made in cross sections neither round or square. Customer – fabricator interaction leads to cross sections that can be fed into machines that fabricate the contact or connector. Generally, production runs are longer, less scrap is generated, and when necessary the parts can be assembled on a bandolier, which aids in plating and assembly. The final product is lighter, but the consumption of copper alloy is actually increased, because of the expanded market.

1. Introduction

The importance of copper and its alloys to today's society is well documented in the articles on → Copper and on → Copper Alloys. Copper compounds, although they represent a small fraction of total copper production, play an important and varied role in industry and agriculture. One of the oldest known fungicides was copper-based and was used extensively in the early part of the century. The last 20 years have brought about a resurgence in the use of copper-based fungicides partly because of a lack of tolerance by fungi to copper and also because of its relatively low toxicity to higher plants and animals (see, however, Chaps. 7 and 9). Although copper is an essential trace element for higher plants and animals, it is acutely toxic in higher doses. Copper compounds are used as nutritional additives in animal feeds and fertilizers, and are found in a variety of dietary supplements. Copper salts are used in the control of algae in lakes and ponds, and the oxides are used in antifouling paints and coatings. Copper acetoarsenite, Paris green, is used as an insecticide, and copper chromium arsenate is an effective alternative to creosote for the preservation of wood.

Copper and its compounds are used catalytically in numerous organic reactions, e.g., polymerization, isomerization, and cracking reactions. They are used in the textile and dye industries in the preparation of rayon and acrylonitrile, as mordants and oxidants in textile dyeing and printing, and in the preparation of azo dyes. Copper compounds are used as pigments in glass, ceramics, porcelains, varnishes, and artificial gems, and in the manufacture of the copper phthalocyanine pigments. Copper salt solutions are used for electroplating, in brazing and burnishing preparations, and as brighteners for aluminum. Solutions of copper(I) complexes are used to selectively absorb carbon monoxide, butadiene, and alkenes from gas streams. In the petroleum industry, copper compounds are used as deodorizing (desulfurization) and purifying agents. Copper(II) carbonate is used in drilling muds to protect against release of poisonous hydrogen sulfide gas, and copper(I) iodide is used in acid muds to bind corrosion inhibitors to the iron drills. More recent applications of copper compounds are in pollution control and solar technology.

The multitude of applications of copper compounds in the biosphere is largely responsible for the extent of academic interest in them. Also, the facile reduction – oxidation of the copper(I) – copper(II) couple, the ease of theoretical treatment of the d^9 copper(II) system, and the varied

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a07_567

stereochemistries and magnetic behaviors associated with copper ions enhance their theoretical appeal. Since this treatment of copper compounds is primarily from an industrial perspective, the reader whose interest is academic is referred to the classic references [1–4] as well as to more recent materials [5–11] that are attune to the subtle chemistries of copper and its compounds. Compounds of primary industrial importance (Chaps. 3 and 4) are distinguished from compounds of minor importance (Chap. 5) in this article.

2. The Copper Ions

Copper, Cu [*7440-50-8*], M_r 63.546, $[Ar]3d^{10}4s^1$, is a member of the first transition series. It is classified as a transition element in the broader definition because the copper(II) valence state, $[Ar]3d^9$, comprises such a large proportion of the defined chemistry of copper. Copper in its compounds exists primarily in two oxidation states, + 1 and + 2. Although copper(0) and copper(III) compounds have been identified, they are not presently of commercial importance. The stabilities of the various valence states of copper are illustrated by the following standard reduction potentials:

	E_0
$Cu^+ + e \longrightarrow Cu^0$	+ 0.52 V
$Cu^{2+} + 2e \longrightarrow Cu^0$	+ 0.34 V
$Cu^{2+} + e \longrightarrow Cu^+$	+ 0.15 V
$Cu^{3+} + e \longrightarrow Cu^{2+}$	+ 1.80 V

From the above, it is seen that

$$2\,Cu^+ \longrightarrow Cu^0 + Cu^{2+} \quad \Delta E_0 = -0.37\,V$$

with $pK = -5.95$

In other words, the free copper(I) ion does not exist to any appreciable extent in aqueous solution. In the presence of ligands such as ammonia, chloride, or cyanide, solutions of copper(I) can be prepared that are stable with respect to disproportionation. For example, the colorless solution of tetraamminedicopper(I) sulfate is prepared readily by contact of blue tetraamminecopper(II) sulfate with metallic copper in the absence of air. Upon acidification with sulfuric acid, copper powder and a copper(II) ammonium sulfate solution are produced. The insoluble copper(I) chloride can be produced by sulfuric acid acidification of a copper(I) ammine chloride solution. If the solution is acidified with hydrochloric acid, a solution of $[CuCl_2]^-$, $[CuCl_3]^{2-}$, or $[CuCl_4]^{3-}$ species is produced, depending on chloride concentration. Copper(I) chloride is stable to water because of its insolubility, which is a result of the polymeric structure that arises from the chloride's ability to bridge copper. This contrasts with the sulfate's inability to coordinate or bridge strongly. Consequently, copper(I) sulfate can be produced only in nonaqueous media.

The electronic structure of the copper(I) ion is $[Ar]3d^{10}$. The compounds are diamagnetic and colorless except where charge-transfer bands arise. Copper(I) is isoelectronic with zinc(II) and the preferred stereochemistries are similar. As a result of the filled 3*d* level, no ligand field stabilization occurs and electronic distortions are minimized. The stereochemistry around the copper(I) ion is determined mainly by the size of the anions, as well as by the electrostatic and covalent bonding forces. The preferred stereochemistry is tetrahedral, with linear and trigonal planar compounds also being common.

The majority of copper(II) compounds exhibit square planar or distorted octahedral configurations about the copper ion. The $3d^9$ electronic structure gives rise to the classic example of Jahn – Teller distortion in which the four planar metal – ligand distances are smaller than the two axial distances. Copper(II) ions are also found in distorted tetrahedral and various five-coordinate environments.

The copper(II) ion, $[Ar]3d^9$, is predominantly blue or green, and the unpaired 3*d* electron results in magnetic phenomena. In most copper compounds, the unpaired electrons of the copper ions are sufficiently isolated from each other so that the compounds exhibit paramagnetic behavior. However, there are many polynuclear copper compounds in which the spins are coupled, which lowers the magnetic moment. The coupling may be so weak that it must be observed near the absolute zero of temperature, or it may be strong enough to render the compound diamagnetic at room temperature or above.

3. Basic Copper Compounds

3.1. Copper(I) Oxide

Cu_2O [*1317-39-1*], M_r 143.09, *mp* 1235 °C, d_4^{25} 5.8 – 6.2, decomposes above 1800 °C. It occurs in nature as the red or reddish brown mineral cuprite with a cubic or octahedral crystal morphology. Depending on the method of preparation and particle size, the synthetic material is yellow, orange, red, or purple. The yellow material has erroneously been referred to as copper(I) hydroxide, but X-ray diffraction patterns indicate that there are no differences in the crystal structures of the colored forms. Their thermodynamic data are as follows: c_p (298 K) 429.8 J kg^{-1} K^{-1}, c_p (290 – 814 K) 519.2 J kg^{-1} · K^{-1}, c_p (290 – 1223 K) 565.2 J kg^{-1} K^{-1}, $\Delta H°$ (25 °C) – 166.6 kJ/mol. Copper(I) oxide is stable in dry air but slowly oxidizes to copper(II) oxide [*1317-38-0*] in moist air. It is practically insoluble in water but dissolves in aqueous ammonia. In excess hydrochloric acid, soluble copper(I) chloride complexes are formed; however, in dilute sulfuric or nitric acids, disproportionation to the soluble copper(II) salts and copper powder results.

Production. Copper(I) oxide is produced easily by a variety of methods; its instability with respect to oxidation requires careful consideration. Copper(I) oxide produced pyrometallurgically is usually coated with isophthalic acid or pine oil to preserve its integrity [12]. Hydrometallurgically produced material can be stabilized by mixing the particle slurry with glue, gelatin, casein, or dextrin before drying [13–16].

Pyrometallurgical Processes. Copper(I) oxide is formed when copper powder is heated above 1030 °C in air; to prevent further oxidation, it must be cooled quickly in an inert atmosphere. To allow for lower temperature production of copper(I) oxide, carbon can be blended with copper(II) oxide and heated to 750 °C in an inert atmosphere. The material must be stabilized by coating the formed particles with isophthalic acid or pine oil [12]. A more stable copper(I) oxide results when stoichiometric amounts of copper powder and copper(II) oxide are blended, heated to 800 – 900 °C in an inert atmosphere, and allowed to cool. The production can be effected at lower temperature if ammonia or certain ammonium salts are added to the blend [17–19]. The autoclave oxidation of copper metal at 120 °C and about 0.6 MPa gauge pressure with air in the presence of water and small amounts of sulfuric and hydrochloric acids produces a red, pigment-grade product [20]. By varying the pressure and temperature, considerable differences in particle size, coloring, apparent bulk density, and buoyancy have been found.

Hydrometallurgical Processes. Tetraamminedicopper(I) sulfate, $Cu_2(NH_3)_4SO_4$, prepared by leaching an excess of copper with a solution of ammonia and ammonium sulfate, with air as the oxidant, yields a red copper(I) oxide upon acidification to pH 3 – 5 [21]. The less corrosive ammonium carbonate leach system in which $Cu_2(NH_3)_4CO_3$ is produced is more common (see page 5). Upon vacuum distillation, a very stable red Cu_2O product remains [21]. If sodium hydroxide is added to the leach liquor, a yellow microcrystalline powder is precipitated [22]. When the yellow Cu_2O is heated in an excess of sodium hydroxide, it is converted to an orange material of somewhat larger particle size.

Steam stripping of the copper(I) ammine carbonate solution yields a brown, impure product [23] which can be converted to a red material by washing it in an organic acid, e.g., formic or acetic acid [24]. An impure, brown product can also be converted to a red material by boiling it in 20 % sodium hydroxide solution [25].

If a saturated solution of copper(I) ammine carbonate is agitated over copper metal, a layer of red copper(I) oxide is continuously produced which can be broken loose and recovered [26]. When copper salts are leached with chelating agents such as ethylenediaminetetraacetic acid [27] or ammonia [28] under pressure of carbon monoxide or hydrogen, and sodium hydroxide is subsequently added, a relatively stable, yellow copper(I) oxide is obtained; the reaction is catalyzed by an alkali metal iodide [29].

The reduction of a boiling slurry of basic copper(II) sulfate with sulfur dioxide at a pH of about 3 produces a reddish product [30]. Red copper(I) oxide has also been prepared by mixing a slurry of basic copper(II) sulfate with neutral copper(II) sulfate and adding sodium sulfite

to a pH of 5.2. The mixture is then acidified to pH 3.5 – 5 and heated to boiling. The intermediate copper(I) sulfite slurry is decomposed to copper(I) oxide and sulfurous acid. Alkali is subsequently added to maintain a pH of 2.6 – 2.8 [31].

When a solution of copper(I) chloride and sodium chloride is neutralized with sodium hydroxide and then heated to 138 °C under pressure, a red copper(I) oxide is obtained which has an average particle diameter of about 2.5 µm [32]; an orange product (about 1-µm particles) is prepared by neutralizing the solution to pH 8.5 at 60 °C [33]. Simultaneous mixing of copper(I) chloride solutions with sodium chloride and sodium hydroxide solution in the presence of copper(I) oxide seed crystals at a controlled pH of 10.0, 55 °C, and under nitrogen, gives a reddish purple material (average diameter 48 µm). At pH 7.0, a yellow material is obtained with an average particle size of 0.4 µm [34].

The *electrolytic production* of copper(I) oxide between copper electrodes in brine yields a yellow product at room temperature. At higher temperature, an orange or red material is produced.

Uses. The largest commercial use of copper(I) oxide is in antifouling paints for boat and ship bottoms; it is an effective control for barnacles and algae. The yellow or orange copper(I) oxide is used as a seed and crop fungicide, and the red material is used as a pigment in ceramic glazes and glass. Copper(I) oxide is also used in rectifiers and in brazing. Numerous organic reactions are catalyzed by copper(I) oxide, and it is an effective absorbent for carbon monoxide.

Analysis and Specifications. The ASTM approved analysis and specification for pigment-grade copper(I) oxide [35] and the military specification for the pigment grade [36] are listed in Table 1.

Table 1. Specifications for pigment-grade copper(I) oxide

Assay	Mass fraction, %	
	Navy I [36], [37]	Navy II [36]
Copper(I) oxide	97.0	90.0
Total copper (min.)	86.0	80.0
Reducing power (min.)	97.0	90.0
Nitric acid-insolubles (max.)	0.3	0.3
Chloride (max.)	0.4	0.4
Sulfate (max.)	0.1	0.1
Zinc oxide (max.)	–	10.0
Other metals (max.)	0.5	0.5
Acetone-soluble material (max.)	0.5	0.5

3.2. Copper(II) Oxide

CuO [*1317-38-0*], M_r 79.54, *mp* 1330 °C, d_4^{25} 6.48, occurs in nature as the black minerals tenorite (triclinic crystals) and paramelaconite (tetrahedral, cubic crystals). Commercially produced copper(II) oxide is usually black, although a brown product (particle size $< 10^{-6}$ m) can also be produced. Thermodynamic data: c_p (298 K) 531.1 J kg^{-1} K^{-1}, c_p (290 – 1253 K) 682.4 J kg^{-1} · K^{-1}, $\Delta H°$ (25 °C) −155.3 kJ/mol. Copper(II) oxide is stable to air and moisture at room temperature. It is virtually insoluble in water or alcohols. Copper(II) oxide dissolves slowly in ammonia solution but quickly in ammonium carbonate solution; it is dissolved by alkali metal cyanides and by strong acid solutions. Hot formic acid and boiling acetic acid solutions readily dissolve the oxide. Copper(II) oxide is decomposed to copper(I) oxide and oxygen at 1030 °C and atmospheric pressure; the reduction can proceed at lower temperature in a vacuum. Hydrogen and carbon monoxide reduce copper(II) oxide to the metal at 250 °C and to copper(I) oxide at about 150 °C. Ammonia gas reduces copper(II) oxide to copper metal and copper(I) oxide at 425 – 700 °C [17].

Production. Copper(II) oxide can be prepared *pyrometallurgically* by heating copper metal above 300 °C in air; preferably, 800 °C is employed. Molten copper is oxidized to copper(II) oxide when sprayed into an oxygen-containing gas [37]. Ignition of copper(II) nitrate trihydrate [*10031-43-3*] at about 100 – 200 °C produces a black oxide. Basic copper(II) carbonate [*12069-69-1*], when heated above 250 °C, produces a black oxide if a dense carbonate is employed; a brown material is produced when the light and fluffy carbonate is used. An alkali-free oxide can be prepared by ignition of copper(II) carbonate produced from ammonium carbonate and a copper(II) salt solution. Copper(II) hydroxide [*20427-59-2*], when heated above 100 °C, is converted to the oxide.

Figure 1. Process flow diagram for production of copper(II) oxide from ammonia – ammonium carbonate leach
a) Leach vat; b) Filter; c) Treatment tank; d) Strip tank; e) Press; f) Bag house; g) Drying kiln

Hydrometallurgy is the most common method for the production of copper(II) oxide. A solution of ammonia and ammonium carbonate in the presence of air effectively leaches metallic copper; the process is represented by the following reactions:

$$2\,Cu + 1/2\,O_2 + 2\,NH_3 + (NH_4)_2CO_3 \longrightarrow [Cu_2(NH_3)_4]CO_3 + H_2O$$

$$2\,NH_3 + (NH_4)_2CO_3 + [Cu_2(NH_3)_4]CO_3 + 1/2\,O_2 \longrightarrow 2\,[Cu(NH_3)_4]CO_3 + H_2O$$

$$Cu + [Cu(NH_3)_4]CO_3 \longrightarrow Cu_2(NH_3)_4CO_3$$

The second and third reactions proceed readily; the first is slow. Consequently, in batch operations the leach is usually begun with a small charge of the copper solution, but continuous operations offer significantly improved rates. The leach liquor is then filtered to remove iron impurities and metallic copper, and is subsequently oxidized by air sparging. If necessary, lead and tin are removed by treatment with strontium, barium, or calcium salts [38–41]. The solution is filtered again and stripped of ammonia and carbon dioxide by steam injection or pressurized boiling to produce a black copper(II) oxide [38]. The ammonia and carbon dioxide are recycled for further use. The process is illustrated in Figure 1. Alternatively, the leach liquor can be treated with strong alkali to precipitate the intermediate copper(II) hydroxide, and then boiled to remove ammonia, with subsequent decomposition of the hydroxide to the black oxide.

The copper(II) ammine sulfate and chloride systems are treated similarly although they are utilized much less frequently because of their highly corrosive nature. However, the copper ammine chloride system, a byproduct of circuit board etching, is recycled out of economic and environmental necessity to copper(II) oxide [42] (see Chap. 6).

Uses. Copper(II) oxide is used as a precursor to a number of copper(II) salts. One of the largest commercial applications is in the production of compounds for wood preservation. Copper(II) oxide is also used extensively as a feed additive and as a pigment in glass, ceramic, and porcelain enamels [43]. In combination with manganese dioxide, it is used as an oxidative catalyst for exhaust gas [44], in the removal of NO_x, CO, and O_3 [45], [46], and in the purification of formaldehyde-containing waste gas [47]. Supported on aluminum phosphate, copper(II) oxide is active in reducing tar and polycyclic hydrocarbons in smoke by absorption and catalytic conversion [48]. Copper(II) oxide is used as a catalyst in the preparation of acrylates [49] and in the production of magnetic storage devices [50]. It has limited application in the petroleum industry as a gas sweetener and is used in welding fluxes for bronze.

Analysis and Specifications. Electrolytic deposition from a solution or iodometric analysis with sodium thiosulfate is standard for copper determination [51]. The technical specification is shown in Table 2.

Table 2. Typical analysis of commercial copper(II) oxide

Assay	Mass fraction, %
Copper	78.5
Iron	0.09
Lead	0.08
Water	0.10
Nitric acid-insolubles	0.10
Zinc	0.05
Surface area, m^2/g	10.0

3.3. Copper(II) Hydroxide

$Cu(OH)_2$ [*20427-59-2*], M_r 97.54, d_4^{25} 3.37, $\Delta H°$ (25 °C) 446.7 kJ/mol, decomposes over 100 °C or over 50 °C in the presence of an excess of alkali. Copper(II) hydroxide is virtually insoluble in water (0.003 mg/L), and decomposes in hot water to the more stable copper(II) oxide and water:

$$\underset{\text{blue}}{Cu(OH)_2} \longrightarrow \underset{\text{green to brown}}{CuO \cdot H_2O} \longrightarrow \underset{\text{brown to black}}{CuO} + H_2O$$

Copper(II) hydroxide is readily soluble in mineral acids and ammonia solution. When freshly precipitated, it is soluble in concentrated alkali, with the formation of $[Cu(OH)_3]^-$ or $[Cu(OH)_4]^{2-}$. Copper(II) hydroxide is inherently unstable but can be kinetically stabilized by a suitable production method.

Production. There are two classes of copper(II) hydroxide. The first is stoichiometrically rather precise, with a copper content as high as 64 %; the theoretical copper content of $Cu(OH)_2$ is 65.14 %. This class is produced by the ammonia process [52–55], which yields a pure product of relatively good stability and large particle size. The best product results from the addition of strong alkali to the soluble copper(II) ammine complex [52], [55]. A relatively large particle-size product, deep blue in color and high in copper content, is precipitated below 35 °C. The resulting material is fairly stable or can be coated with gelatin to enhance its stability [56].

In the copper(II) hydroxide made by the ammonia process, the solubility of the copper(II) ammine complexes provides for crystallite growth. This affords a large particle size, a limited surface area (point of dehydration), and hence a relatively stable product, in contrast with the unstable product (variable assay) that results from the addition of hydroxide solutions to copper(II) salt solutions at 20 °C or above. The reaction with hydroxide is diffusion-controlled, allowing essentially no time for crystallite growth. The product is obtained as a gelatinous, voluminous precipitate with a large surface area, which is quite unstable and difficult to wash free of impurities. If the same reaction, with the same order of addition, is allowed to occur at 0 – 10 °C, a product of defined particle size and measurable surface area results, with greater stability but low assay.

The second class of copper(II) hydroxide, which represents a "stable" product but has lower assay and greater impurity, is produced from an insoluble precursor such as basic copper(II) carbonate or copper(II) phosphate. The first stable copper(II) hydroxide of this kind was made from copper(II) phosphate with alternate additions of copper(II) sulfate and sodium hydroxide solutions [57]. The process is illustrated by the following series of reactions:

$$3\,CuSO_4 + 2\,Na_3PO_4 \longrightarrow Cu_3(PO_4)_2 + 3\,Na_2SO_4$$
$$Cu_3(PO_4)_2 + 6\,NaOH \longrightarrow 3\,Cu(OH)_2 + 2\,Na_3PO_4$$

The alternate copper(II) sulfate – sodium hydroxide addition is continued through 15 or 20 cycles and yields a stable product with 58 – 59 % copper and 3 – 5 % phosphate. The product has a small particle size and a high surface area, and is used as an agricultural fungicide.

Other stable copper(II) hydroxides of high surface area and fine particle size have been produced more recently [58–60]; the processes include the use of a copper(II) oxychloride precursor in the presence of an anionic surfactant [59] or a magnesium sulfate-precipitated precursor [58]. An electrolytically produced material has also been made by using trisodium phosphate as the electrolyte [61].

The classic Bordeaux slurry of copper(II) sulfate and lime in water has been replaced by a powdered stabilized product. This is obtained by mixing copper(II) nitrate solution and lime, adding cellulose pitch liquor (a waste product of the paper industry), and drying to yield a powder which is effective as a fungicide [62]. Sodium carbonate can be used as the precipitating agent instead of lime [63].

Uses. Copper(II) hydroxide is used as an active precursor in the production of copper(II) compounds. Ammonia-processed copper(II) hydroxide is used in the production of copper(II) naphthenate, copper(II) 2-ethylhexanoate, and copper soaps. Ammonia-processed copper(II) hydroxide is also used in the production of rayon (Schweitzer's reagent) and in the stabilization of nylon. Copper(II) hydroxides of the second class are often used as fungicides because of their small particle size. Copper(II) hydroxide is also used as a feed additive, a catalyst in the vulcanization of polysulfide rubber, and an antifouling pigment.

Analysis and Specifications. Copper is determined iodometrically with sodium thiosulfate [51]. The analysis of typical ammonia-processed copper(II) hydroxide (mass fractions in %) is copper 63.0, iron 0.05, zinc 0.05, lead 0.05, naphthenic acid-insoluble material 2.0, sulfate 0.3.

3.4. Copper(II) Carbonate Hydroxide

Copper(II) carbonate hydroxide, also called basic copper(II) carbonate, occurs in nature as the metastable mineral *azurite* [*12070-39-2*], also called chessylite, a blue, monoclinic crystalline or amorphous powder with a formula approximating $2\,CuCO_3 \cdot Cu(OH)_2$, M_r 344.67, d_4^{24} 3.8, $\Delta H°$ (20 °C) − 87.4 kJ/mol, and *malachite* [*12069-69-1*], green, monoclinic crystals with a formula approximating $CuCO_3 \cdot Cu(OH)_2$, M_r 221.12, d_4^{25} 3.9 – 4.0, $\Delta H°$ (20 °C) − 57.7 kJ/mol. The copper(II) carbonate of commerce, malachite, is also known as Bremen green. Pure copper(II) carbonate, $CuCO_3$, has not been isolated. Copper(II) carbonate is virtually insoluble in water but dissolves readily in aqueous ammonia and alkali metal cyanide solutions. Copper(II) carbonate dissolves quickly in mineral acid solutions and warm acetic acid solution, with the formation of the corresponding copper(II) salt. Malachite is much more stable than copper(II) hydroxide but slowly decomposes to the oxide according to the following reaction:

$$CuCO_3 \cdot Cu(OH)_2 \longrightarrow 2\,CuO + H_2O + CO_2$$

Malachite is rapidly decomposed to the oxide above 200 °C.

Production. Two grades of copper(II) carbonate are available commercially, the light and the dense. The light grade is a fluffy product of high surface area. It is precipitated by adding a copper(II) salt solution, usually copper(II) sulfate solution, to a concentrated solution of sodium carbonate at 45 – 65 °C. Azurite is formed initially, and complete conversion to malachite usually occurs within two hours. The conversion is accelerated by the addition of malachite nuclei to the reactor.

A dark green, dense product results when a copper(II) salt solution is added to a solution of sodium hydrogen carbonate at 45 – 65 °C; conversion to malachite requires about one hour in this case. The density is maximized if the reactor is washed with acid prior to the precipitation to prevent premature nucleation on malachite nuclei. (A less dense product would be produced if malachite nuclei are added to the slurry of azurite.) Solutions of copper(II) salt and sodium carbonate can also be added simultaneously at a pH of 6.5 – 7.0 and a temperature between 45 and 65 °C; conversion to malachite is usually complete within one hour.

When a solution of copper(II) ammonium carbonate is boiled, ammonia and carbon dioxide are expelled from the solution, and a deep green, dense copper(II) carbonate precipitates [38].

Uses. Copper(II) carbonate is used as a precursor in the production of copper salts and soaps. It is used in animal feeds as a source of copper, in the sweetening of petroleum, and in electroplating for the control of pH. Copper(II) carbonate is used as a hydrogenation catalyst and as an accelerator in polymerization reactions. The light grade is somewhat effective as a fungicide and is used as a seed protectant.

Analysis and Specifications. Copper is analyzed by iodometric titration with sodium thiosulfate solution [51]. Table 3 gives typical analyses of light and dense technical-grade copper(II) carbonates.

Table 3. Typical analysis of commercially available copper(II) carbonate hydroxides

Assay	Mass fraction, %	
	Light	Dense
Copper	55.5	55.0
Sulfate	0.6	0.6
Iron	0.1	0.1
Zinc	0.01	0.02
Lead	0.003	0.005
Hydrochloric acid-insoluble material	0.05	0.05
Water	1.0	2.0

Figure 2. Solubility of copper(I) chloride in excess chloride ion solution at different temperatures

4. Salts and Basic Salts

4.1. Copper(I) Chloride

Copper(I) chloride [*7758-89-6*], CuCl, M_r 99.00, *mp* 422 °C, *bp* 1367 °C, d_4^{25} 4.14, $\Delta H°$ (25 °C) − 134.6 kJ/mol, occurs in nature as the colorless or gray cubic-crystal nantokite. The commercially available product is white to gray to green and of variable purity. Copper(I) chloride is fairly stable in air or light if the relative humidity is less than about 50 %. In the presence of moisture and air, the product is oxidized and hydrolyzed to a green product that approaches copper(II) oxychloride, $CuCl_2 \cdot 3\,Cu(OH)_2$[*12356-86-4*]. In the presence of light and moisture, a brown or blue product is obtained. Copper(I) chloride is slightly soluble to insoluble in water, with values from 0.001 to 0.1 g/L being reported. It is readily hydrolyzed to copper(I) oxide by hot water. Copper(I) chloride is insoluble in dilute sulfuric and nitric acids, ketones, alcohols, and ethers, but it quickly dissolves in hydrochloric acid, alkali halide, or ammonia solutions with the formation of complex compounds that are readily oxidized by air. Copper(I) chloride is soluble in solutions of alkali metal cyanides or thiosulfates and of coordinating amines, pyridines, and nitriles, notably, acetonitrile [64]. The increase in solubility of copper(I) chloride with chloride ion concentration illustrated in Figure 2 [65]. When the chloride concentration is decreased by dilution with water, the pure white copper(I) chloride precipitates.

Production. The direct combination of the elements is the most common method of production. The reaction of copper metal and chlorine is not spontaneous at ambient temperature. Once the metal is heated to red heat in the presence of chlorine, the reaction is self-sustaining and requires external cooling to prevent the metal from melting. A number of similar patents exist [66–69] in which copper metal is reacted with chlorine gas to produce a molten copper(I) chloride that is cast and pulverized. The primary difference in conditions is the use of a shaft furnace [66] as opposed to the use of crucibles. The recommended process temperature varies from 450 to 800 °C [66], [67] or 500 to 700 °C [68], [69]. The conditions required for the high-temperature production of a pure copper(I) chloride can be illustrated by the following:

$$Cu + 1/2\,Cl_2 \longrightarrow CuCl \qquad \Delta H = -134.6\,kJ/mol$$
$$Cu + Cl_2 \longrightarrow CuCl_2 \qquad \Delta H = -247.2\,kJ/mol$$
$$CuCl + 1/2\,Cl_2 \longrightarrow CuCl_2 \qquad \Delta H = -122.6\,kJ/mol$$
$$CuCl_2 + Cu \longrightarrow 2\,CuCl \qquad \Delta H = -22\,kJ/mol$$

Higher temperature and excessive contact with copper metal favor the production of a very pure copper(I) chloride. The lowest possible temperature is obviously 422 °C, the melting point of copper(I) chloride. As the temperature approaches the decomposition temperature for the reaction

$$CuCl_2 \longrightarrow CuCl + 1/2\,Cl_2 \ (993\,°C)$$

a product of higher purity is obtained. Operationally, a temperature between 750 and 900 °C is ideal, and results in a product of > 98 % purity. The process of Degussa [67] illustrates a commonly used commercial process for the high-temperature production of copper(I) chloride; Figure 3 shows a suitable crucible for the production of technical-grade copper(I) chloride. Once the reaction is initiated, chlorine and copper metal (shot, chopped wire, or briquettes) are added continuously. As the molten product is formed on the surface of the upper metal layer, it flows by gravity down through the porous copper bed to effect further reduction of any copper(II) chloride, and out the exit port onto a rotating table where the product is allowed to cool and solidify. The flakes that form are packaged as is or ground to a powder and packaged. Because of the high temperature during the reaction and the volatility of copper(I) chloride, the exit port must be vented to a caustic scrubber. When the molten product is allowed to fall onto a high-speed, horizontally rotating disk constructed of quartz, graphite, or porcelain, small prills of uniform size are produced [70]. The product is spun out onto a water cooled diaphragm and collected. If the copper is contaminated with oxides, hydrogen chloride gas should be added to the chlorine gas stream to prevent the production of basic copper(II) chlorides that would contaminate the product [66].

Figure 3. Crucible used in the production of copper(I) chloride

If the product is packaged quickly and sealed properly, no extreme precautions are required. Otherwise, the product must be stored under nitrogen to preserve its integrity or coated with mineral oil as a barrier to moisture.

Copper(I) chloride is also produced hydrometallurgically by the reduction of copper(II) in the presence of chloride ions [71]:

$$2\,CuCl_2 + Na_2SO_3 + H_2O \longrightarrow 2\,CuCl + Na_2SO_4 + 2\,HCl$$

Other reducing agents can be used, such as metallic copper, sulfurous acid, hydroxylamine, hydrazine, or phosphorous acid. The copper(I) chloride solution is produced, for example, by mixing a copper(II) chloride solution with metallic copper in the presence of hydrochloric acid or sodium chloride. The colorless to brown solution is stable only in the absence of air. Continuous preparations of copper(I) chloride solutions have been developed [72], [73]. When they are diluted with water, a white crystalline material precipitates which can be vacuum dried or washed with sulfurous acid, then with alcohol and ether, and carefully dried. Zinc has also been used as a reducing agent in a more recent process [74].

Production of copper(I) chloride by treatment of ores with iron(III) chloride solutions [75], [76] and recovery of the product through chlorination in pit furnaces above 800 °C [77] have also been attempted.

Uses. Copper(I) chloride is used as a precursor in the production of copper(II) oxychloride and copper(I) oxide, as well as fine copper powder [78]. The production of silicone polymers, the vulcanization of ethylene – propene rubbers (EPDM) [79], and acrylonitrile production are other applications. Copper(I) chloride is also used in the purification of carbon monoxide gas [80–83] and the production of phthalocyanine pigments [84], [85]. More recently, copper(I) chloride has been found to be an effective catalyst in the production of dialkyl carbonates [86–88].

Analysis and Specifications. Copper(I) chloride is analyzed according to [51]. Table 4 lists specifications for technical- and reagent-grade material.

Table 4. Specifications for copper(I) chloride

Assay	Mass fraction, %	
	Technical-grade	Reagent-grade
Copper (min.)	97.0	90.0
Acid-insolubles (max.)	0.1	0.02
Iron (max.)	0.01	0.005
Sulfate (max.)	0.3	0.10
Arsenic (max.)	–	0.001
Not precipitated by H_2S as sulfate (max.)	–	0.2

4.2. Copper(II) Chloride

Copper(II) chloride [*7447-39-4*], $CuCl_2$, M_r 134.45, *mp* (extrapolated) 630 °C, d_4^{25} 3.39, begins to decompose to copper(I) chloride and chlorine at about 300 °C. The often reported melting point of 498 °C is actually a melt of a mixture of copper(I) chloride and copper(II) chloride. Decomposition to copper(I) chloride and chlorine is complete at 993 °C. The deliquescent monoclinic crystals are yellow to brown when pure; their thermodynamic data are as follows: c_p (298 K) $-579.2\,J\,kg^{-1}\,K^{-1}$, c_p (288–473 K) $-621.7\,J\,kg^{-1}\,K^{-1}$, c_p (288–773 K) $-661.9\,J\,kg^{-1}\,K^{-1}$, $\Delta H°$ (25 °C) -247.2 kJ/mol. In moist air, the dihydrate is formed. Figure 4 shows the solubility of copper(II) chloride in water and hydrochloric acid at two temperatures [89]. At higher concentrations of hydrogen chloride, $[CuCl_3]^-$ and $[CuCl_4]^{2-}$ complexes are formed. Copper(II) chloride is easily soluble in methanol and ethanol and moderately soluble in acetone.

Figure 4. Solubility of copper(II) chloride in hydrochloric acid solutions at different temperatures

The more common commercial form of copper(II) chloride is the dihydrate [*10125-13-0*], $CuCl_2 \cdot 2\,H_2O$, M_r 170.45, *mp* around 100 °C (with decomposition to the anhydrous form). This occurs in nature as blue-green orthorhombic, bipyramidal crystals of eriochalcite, d_4^{25} 2.51. Its solubility characteristics are proportionally similar to those of the anhydrous form. In moist air the dihydrate deliquesces, and in dry air it effloresces.

Production. Because of the relative stabilities of copper(I) chloride and copper(II) chloride at high temperature, it is improbable that a pure anhydrous copper(II) chloride can be prepared by excessive chlorination of copper in a melt, even though such methods have been reported. The most common method for the production of anhydrous copper(II) chloride is by dehydration of the dihydrate at 120 °C. The product must be packaged in air-tight or desiccated containers.

The dihydrate can be prepared by the reaction of copper(II) oxide, copper(II) carbonate, or copper(II) hydroxide with hydrochloric acid and subsequent crystallization. Commercial production of copper(II) chloride dihydrate uses a tower packed with copper. An aqueous solution is circulated through the tower. Sufficient chlorine is passed into the bottom of the tower to oxidize the copper completely [72], [73]; to prevent hydrolysis [precipitation of copper(II) oxychloride] of concentrated copper(II) chloride solutions, they are kept acidic with hydrochloric acid. The tower can be operated batchwise or continuously; Figure 5 (see next page) shows the continuous operation. A hot, concentrated liquor is circulated continuously through the tower, and the overflow from the tower is passed through a crystallizer where the liquor is cooled; the product is then centrifuged, dried, and packaged. The addition of hydrogen chloride is pH controlled; the addition of water is controlled by specific gravity. Copper is added daily or twice daily, as needed.

Uses. Copper(II) chloride dihydrate is used in the preparation of copper(II) oxychloride [90], [91]. It serves as a catalyst in numerous organic chlorination reactions such as the production of vinyl chloride [92] or 1,2-dichloroethane [93]. Copper(II) chloride dihydrate is used in the textile industry as a mordant and in the

Figure 5. Reactor for the production of copper(II) chloride solutions

petroleum industry to sweeten sulfidic crude oil. Copper(II) chloride solutions are used for plating copper on aluminum, and in tinting baths for tin and germanium. Copper(II) chloride dihydrate is used as a pigment in glass and ceramics, as a wood preservative, and in water treatment.

Analysis and Specifications. Copper is analyzed iodometrically with sodium thiosulfate [51]. A typical analysis of technical-grade copper(II) chloride dihydrate (mass fractions in %) is as follows: copper(II) chloride dihydrate 99.0 (min.), iron 0.02, zinc 0.05, sulfate 0.05, water-insoluble material 0.01, material not precipitated by hydrogen sulfide as sulfate 0.15.

4.3. Copper(II) Oxychloride

Copper(II) oxychloride, $Cu_2Cl(OH)_3$ [*1332-65-6*], M_r 213.56, is usually written as $CuCl_2 \cdot 3\,Cu(OH)_2$. The trade name is copper oxychloride or basic copper chloride; the internationally accepted name (IUPAC) is dicopper chloride trihydroxide. Copper oxychloride is found in nature as the minerals paratacamite, green hexagonal crystals, and atacamite, green rhombic crystals, d_4^{25} 3.72 – 3.76 [94]. It is virtually insoluble in water, dissolves readily in mineral acids or warm acetic acid, and is soluble in ammonia and alkali-metal cyanide solutions. The green oxychloride is converted into blue copper(II) hydroxide in cold sodium hydroxide solution [59] and into the oxide in hot sodium hydroxide solution. With a lime suspension, copper oxychloride is converted into the blue calcium tetracuproxychloride, calcium tetracopper(II) chloride tetrahydroxide, $CaCl_2 \cdot 4\,Cu(OH)_2$ [95]. It is decomposed to the oxide at 200 °C.

Production. Copper(II) oxychloride is most often prepared commercially by air oxidation of copper(I) chloride solutions [90], [91], [96], [97]. For this purpose, a concentrated sodium chloride solution containing about 50 g/L copper(II) is contacted with copper metal to produce a solution containing about 100 g/L copper(I). The copper(I) chloride – sodium chloride solution, with or without the copper metal, is then heated to 60 – 90 °C and aerated to effect oxidation:

$$CuCl_2 + Cu \longrightarrow 2\,CuCl$$

$$6\,CuCl + 3\,H_2O + 3/2\,O_2 \longrightarrow CuCl_2 \cdot 3\,Cu(OH)_2 + 2\,CuCl_2$$

The mother liquor is separated from the precipitate and recycled into the process. The particles that are obtained by the above process are generally less than 4 µm in diameter and are suitable as crop fungicides. The particle size can be reduced further by increasing the agitation during oxidation and by utilizing a lower temperature [96]. Also, spray-drying of the product slurry gives a micronized product [98] as a result of deagglomeration of the material. Copper(II) oxychloride can also be prepared by reaction of a copper(II) chloride solution with sodium hydroxide [94]:

$$4\,CuCl_2 + 6\,NaOH \longrightarrow CuCl_2 \cdot 3\,Cu(OH)_2 + 6\,NaCl$$

or by reaction of a copper(II) chloride solution with freshly precipitated, hydrated copper(II) oxide [99]:

$$CuCl_2 + 2\,NaOH \longrightarrow CuO \cdot H_2O + 2\,NaCl$$

$$CuCl_2 + 3\,CuO \cdot H_2O \longrightarrow CuCl_2 \cdot 3\,Cu(OH)_2$$

Copper oxychloride has also been produced as a byproduct in the electrolytic production of copper(I) chloride [100].

Uses. Copper oxychloride is used primarily as a foliar fungicide [90], [101–105]; it is also used as a pigment.

Analysis and Specifications. A typical analysis of technical-grade copper(II) oxychloride (mass fractions in %) is as follows: copper 56.0, chloride 14.0 – 15.0, sulfate 2.0 – 2.5, hydroxide 22.5 – 23.5, water 3.0 – 6.0. Copper is analyzed by iodometric titration with sodium thiosulfate [51].

4.4. Copper(II) Sulfates

4.4.1. Copper(II) Sulfate Pentahydrate

$CuSO_4 \cdot 5\,H_2O$ [*7758-99-8*], M_r 249.61, d_4^{25} 2.285, c_p (273 – 291 K) 1126 J kg^{-1} K^{-1}, $\Delta H°$ (25 °C) − 850.8 kJ/mol, bluestone, blue vitriol, is found in nature as the mineral chalcanthite, blue trichlinic crystals that can be ground to a light blue powder. Copper(II) sulfate pentahydrate slowly effloresces in dry air or above 30.6 °C with the formation of the trihydrate, $CuSO_4 \cdot 3\,H_2O$. At 88 – 100 °C the trihydrate is produced more quickly. Thermal analysis of the pentahydrate gives the following:

$$CuSO_4 \cdot 5\,H_2O \xrightarrow{88\,°C} CuSO_4 \cdot 3\,H_2O \xrightarrow{114\,°C} CuSO_4 \cdot H_2O$$
$$\xrightarrow{245\,°C} CuSO_4 \xrightarrow{340\,°C} 3\,Cu(OH)_2 \cdot CuSO_4 \xrightarrow{600-650\,°C} CuO$$

Above about 114 °C, the monohydrate is formed, and between about 245 and 340 °C, the anhydrous product $CuSO_4$, results. Figures 6 A and 6 B show solubility of $CuSO_4$ in water and density of the solution as a function of temperature and sulfuric acid concentration [106], [107]. The pentahydrate can be crystallized from the solution either by addition of sulfuric acid or by evaporation. Although the addition of sulfuric acid appears to be more economical, the concentration of the solution by evaporation is preferred because the crystals obtained from a "neutral" (pH 3.5 – 4.0) medium are less prone to hard cake formation than the acid crystals. As the particle size of the pentahydrate decreases, the tendency toward hard cake formation increases, and the necessity to increase the pH during crystallization is enforced. When a free-flowing, commercial product of fine particle size is required, such alkaline additives as calcium oxide or calcium stearate must be incorporated into the final product to assure flowability. The incorporation of excess acid into the product accelerates the in situ dehydration of the pentahydrate and pro-

Figure 6. Saturated solutions of copper(II) sulfate

Reprinted with permission [107]

motes hard cake formation. Lower temperature and lower humidity slow the caking process.

Copper(II) sulfate pentahydrate is soluble in methanol (15.6 g/100 mL solution) but insoluble in ethanol. It readily forms soluble alkaline complexes at sufficiently high concentrations of amines or alkali cyanides (see Chap. 5), but basic sulfates are precipitated from solution by ammonia at an intermediate pH (about 4.2 – 6.8).

Copper(II) sulfate pentahydrate is the most commonly used copper compound because of the economics and the availability of starting materials, the ease of production, and the extent of byproduct utilization (primarily copper electrowinning liquors).

Production. Copper(II) sulfate pentahydrate is prepared most easily by the reaction of a basic copper(II) compound with a sulfuric acid solution (100 – 200 g/L H_2SO_4), e.g.:

$$CuO + H_2SO_4 \longrightarrow CuSO_4(aq) + H_2O$$

Copper metal, sulfuric acid, and air are the most common starting materials for the production of copper sulfate pentahydrate:

$$Cu + H_2SO_4 + 1/2\,O_2 \xrightarrow{65-100\,^{\circ}C} CuSO_4(aq) + H_2O$$

Harike Process. The Harike process [108] is the best commercial example of the preceding reaction (Fig. 7). Blister shot copper up to 25 mm in diameter is added to the reaction tower (2.9 m^2 cross – sectional area) to give a bed of copper metal 2.74-m high. Two different reaction conditions are given in Table 5. Condition A allows for the production of concentrated copper(II) sulfate solutions and subsequent crystallization from acid media. Condition B gives a concentrated neutral solution of copper(II) sulfate that can be crystallized or diluted with water and used for direct production of other copper products. The rate of oxygen consumption by the system is directly proportional to the mass of copper metal

Figure 7. Harike tower process for production of copper(II) sulfate solutions
a) Heat exchanger; b) Circulation pump; c) Air inlet; d) Copper input

dissolved. Air flows of 46 $m^3\,h^{-1}\,m^{-2}$ are used in order to fill with air the voids that are created by the packing of the copper shot. The solution is circulated cocurrently with the air flow to wet the particles continuously and enhance mixing of the solution with the copper metal. If the air flow is decreased and the voids in the copper metal bed are not filled sufficiently, the hot acid solution oxidizes the copper metal in the absence of air with the formation of a copper sulfide film. This film renders the copper metal inert to further oxidation and would lower the efficiency of the tower. On the other hand, an increase in air flow above 46 $m^3\,h^{-1}\,m^{-2}$ decreases the fraction of oxygen consumed and would also result in a lowered efficiency of the tower. If an increased production (greater oxygen consumption) with good tower efficiencies is required, the height of the tower must be increased. This would also be necessary if a copper metal of lower surface area was used such as scrap copper instead of the blister shot copper. The use of cement copper and fine chopped wire creates insufficient voids for adequate air passage; such fine copper must be leached in agitated vessels.

Two-Tower Process. Another commercial method for the preparation of copper(II) sulfate pentahydrate utilizes two towers filled with copper shot. One of the towers is filled with a sulfuric acid solution, whereas the other is sparged with air and steam to oxidize the surface of the copper metal and form a layer of copper(II) oxide. The solution is pumped alternately to the other tower to dissolve the layer of oxide while the now drained tower is sparged with air and steam. This process is continued until the desired copper(II) sulfate concentration is reached.

The Trickle method is also used commercially: a copper-filled tower is continuously sprayed from the top with leach liquor from an adjacent reservoir. The liquor drains through the tower and is pumped back to the reservoir. Steam and air are sparged continuously into the tower from the bottom. The process is continued until the copper sulfate solution has the desired concentration.

Solvent Extraction. Copper(II) sulfate pentahydrate is produced from alkaline ammoniacal copper(II) solutions by solvent extraction [107], [109]. The alkaline copper(II) solution is first contacted with an organic extractant that is selective to copper. One of the most common extractants can be represented by the following general formula:

where R and R′ are preferably unsaturated alkyl groups and R″ is preferably hydrogen [110].

$$[Cu(NH_3)_4]^{2+}\,(aq) + 2\,RH \longrightarrow CuR_2 + 2\,NH_3\,(aq) + 2\,NH_4^+\,(aq)$$

The now copper-barren aqueous layer is continuously separated from the copper-containing organic layer which is subsequently contacted with a sulfuric acid solution:

$$CuR_2 + H_2SO_4 \longrightarrow CuSO_4 + 2\,RH$$

The saturated copper(II) sulfate liquor produced is cooled or concentrated by evaporation to crystallize the pentahydrate. The copper-barren ammonia–ammonium salt solution is continuously returned to the copper leach tank. Figure 8 (see next page) shows a flow diagram for a typical solvent extraction ammonia leach circuit utilizing mixer–settlers. With the exception of small quantities of wash water and loss of ammonia, the plant produces no effluent. Also, this process allows for lower overall energy input than acid dissolution, primarily as a result of the more facile oxidation of copper metal in ammoniacal solutions. Ion-exchange resins are

Figure 8. Flow diagram for a solvent extraction plant

used to recover and concentrate copper from the solution [111], [112]. Elution of the resins with sulfuric acid produces copper(II) sulfate solutions.

Byproduct Recovery. About 20 – 30 % of the total copper(II) sulfate pentahydrate produced comes from the electrowinning industry as a byproduct. When the impurity content of the electrowinning liquors is too high to make cathode copper, they are concentrated and crystallized [113]. The product is suitable for most agricultural applications. Acidic copper(II) sulfate etching wastes are neutralized with a copper sludge, filtered, and concentrated to produce an agricultural-grade pentahydrate [114], [115].

Uses. The major uses of copper(II) sulfate pentahydrate have been grouped as follows [113]:

Agriculture (feed supplement, soil nutrient, fungicide)	41 %
Industrial algicides	27 %
Mining (flotation activator)	10 %
Electroplating	5 %

In many instances, the copper(II) sulfate pentahydrate is used as an intermediate, e.g., to produce active foliar fungicides such as Bordeaux mixture, tribasic copper(II) sulfate, or copper(II) hydroxide. A substantial amount of copper(II) sulfate pentahydrate is used in combination with sodium dichromate and arsenic acid for the preservation of wood. Copper(II) sulfate pentahydrate is an effective and economical algicide for lakes and ponds. In the mining industry, it is used as a flotation activator for lead, zinc, and cobalt ores. Copper(II) sulfate solutions are often used in the electroplating industry. The compound is also used as a mordant in textile dyeing, in the preparation of azo and formazan dyes, as a pigment in paints and varnishes, for preserving hides and tanning leather, in pyrotechnic compositions, and in synthetic fire logs.

Analysis and Specifications. Typical analyses for various commercially available crystal sizes are shown in Table 6. Table 7 (both see next page) lists specifications for an electroless copper(II) sulfate pentahydrate. The analytical methods for copper(II) sulfates are given in [51].

Table 6. Typical analysis of copper(II) sulfate pentahydrate

4.4.2. Anhydrous Copper Sulfate

$CuSO_4$ [*7758-98-7*], M_r 159.61, occurs in nature as the mineral hydrocyanite [*14567-54-5*]. It is gray to white and has a rhombic crystal morphology. It decomposes to the green basic copper(II) sulfate at 340 °C, and at 600 – 650 °C it decomposes to copper(II) oxide. Some of the properties of the anhydrous salt are as follows: d_4^{25} 3.6, c_p (273 – 291 K) 631.8 J kg^{-1} K^{-1}, c_p (273 – 373 K) 657.3 J kg^{-1} K^{-1}, $\Delta H°$ (25 °C) − 771.6 kJ/mol. The compound is soluble in water (Section 4.4.1), somewhat soluble in methanol (1.1 g/100 mL), but insoluble in ethanol. It readily dissolves in aqueous ammonia and excess alkali metal cyanides, with the formation of complexes. The material is hygroscopic, with conversion to the pentahydrate in moist air below 30 °C.

The anhydrous salt is prepared by careful heating of the pentahydrate salt to 250 °C. It can also be prepared by the reaction of hot concentrated sulfuric acid with copper metal, but purification is rather difficult.

The compound has limited commercial use, but it can be used as a desiccant for removing water from organic solvents and is a sensitive indicator of the presence of moisture in such solvents.

4.4.3. Copper(II) Sulfate Monohydrate

$CuSO_4 \cdot H_2O$ [*10257-54-2*], M_r 175.63, d_4^{20} 3.25, is a whitish powder. The solubility of the monohydrate in water is identical to the pentahydrate on a copper basis. The product is hygroscopic and must be packaged in containers with moisture barriers. It is commercially produced by dehydration of the pentahydrate at 120 – 150 °C. A novel preparation is to triturate stoichiometric ratios of copper(II) oxide and sulfuric acid:

$$CuO + H_2SO_4 \longrightarrow CuSO_4 \cdot H_2O$$

The uses of the monohydrate are analogous to those of the pentahydrate. Although there can be slight economic advantages (primarily freight costs) in using the monohydrate, market acceptance has not been great. Presently, less than 5 % (copper basis) of copper(II) sulfate is marketed in the monohydrate form.

4.4.4. Basic Copper(II) Sulfates

Four distinct basic copper(II) sulfates can be identified by potentiometric titration of a cop-

per(II) sulfate solution with sodium carbonate or sodium hydroxide solution [115], [116]: $CuSO_4 \cdot 3\,Cu(OH)_2 \cdot H_2O$ (langite), $CuSO_4 \cdot 2\,Cu(OH)_2$ (antlerite), $CuSO_4 \cdot 3\,Cu(OH)_2$ (brochantite), and $CuSO_4 \cdot CuO \cdot 2\,Cu(OH)_2 \cdot x\,H_2O$. Their unique crystal morphologies are confirmed by X-ray diffraction.

The most important commercial basic copper(II) sulfate, commonly referred to as *tribasic copper sulfate* [*12068-81-4*], is $CuSO_4 \cdot 3\,Cu(OH)_2$, M_r 452.27, *mp* ca. 380 °C (decomp.), d_4^{25} 3.78, occurs in nature as the green monoclinic mineral brochantite. It is readily soluble in mineral acids, acetic acid solution, and ammonia solution; it is insoluble in water. Above 650 °C it decomposes to copper(II) oxide. If anhydrous copper(II) sulfate is heated cautiously to 650 °C, another naturally occurring mineral is obtained, dolerophane, $CuSO_4 \cdot CuO$, which reacts readily with water at 20 °C to form $CuSO_4 \cdot 3\,Cu(OH)_2 \cdot H_2O$ or at 100 °C to form $CuSO_4 \cdot 2\,Cu(OH)_2$ [117].

Production. Tribasic copper(II) sulfate, the commercially available basic copper(II) sulfate, is most often prepared by the addition of sodium carbonate solution to hot solutions of copper(II) sulfate:

$$4\,CuSO_4 + 3\,Na_2CO_3 + 3\,H_2O \longrightarrow CuSO_4 \cdot 3\,Cu(OH)_2 + 3\,Na_2SO_4 + 3\,CO_2$$

Great variation of particle size can be achieved by control of the precipitation temperature. As the temperature is increased, larger particles with greater bulk density are formed. If a small particle size is desired, lower precipitation temperature should be used. However, as the precipitation temperature is lowered, multiple hydrates and larger amounts of sulfate are incorporated into the product; e.g., around 50 °C, the dried product contains only about 50 % copper. A precipitation temperature around 90 °C is required to make a pure tribasic copper(II) sulfate.

The single largest use of the compound is as a crop fungicide, and small particles are preferred because they give a greater degree of coverage. These small particles can be obtained by high-energy attrition of the product or by carefully controlled precipitation conditions.

Another method of making tribasic copper(II) sulfate is the aeration of a suspension of copper(I) oxide in the presence of stoichiometric quantities of sulfuric acid or copper(II) sulfate [118]:

$$2\,Cu_2O + H_2SO_4 + O_2 + 2\,H_2O \longrightarrow CuSO_4 \cdot 3\,Cu(OH)_2$$

$$6\,Cu_2O + 4\,CuSO_4 + 3\,O_2 + 12\,H_2O \longrightarrow 4\,[CuSO_4 \cdot 3\,Cu(OH)_2]$$

A purified, concentrated solution of copper(II) sulfate containing ammonium sulfate can be neutralized to pH 6.0 – 6.5 with ammonia to give a blue precipitate of approximate stoichiometry $4\,CuSO_4 \cdot 12\,Cu(OH)_2 \cdot 5\,H_2O$. When this is dried, a green tribasic copper(II) sulfate is formed with up to 1 mol of hydration water per mole of tribasic salt [119]; the water content depends on the drying temperature.

A continuous process has been developed in which copper(II) sulfate solutions are neutralized to pH 5.9 at 30 °C by addition of gaseous ammonia to an agitated vessel [120]. A unique, germicidally active, basic copper(II) sulfate whose X-ray diffraction pattern differs from langite and brochantite has been prepared in this way [121].

Reaction of copper(II) sulfate with $Na_3PO_4 \cdot 12\,H_2O$ and sodium hydroxide in aqueous solution gives a fine, blue, basic copper(II) sulfate powder (16 % SO_4, 2.6 % PO_4, and 54.9 % Cu) that is formulated into a germicidal powder.

Tribasic copper(II) sulfate can also be prepared by cautiously heating copper(II) sulfate to 340 °C or by the aeration of a hot copper(II) sulfate solution in contact with copper metal.

Other basic copper(II) sulfates of commercial interest are the classic fungicial mixtures, Bordeaux and Burgundy slurries, in which copper(II) sulfate solution is mixed with lime and soda ash, respectively. They are of variable stoichiometry. More recently, the aqueous Bordeaux suspension has been dried to yield a stable basic copper(II) sulfate powder of variable composition [122].

Uses. As stated earlier, basic copper(II) sulfate is primarily used as a crop fungicide [123], [124]. It has also been utilized as a precursor in the separation of copper from metallic impurities [125].

Analysis and Specifications. The analysis of a typical technical-grade tribasic copper(II) sulfate is (mass fractions in %) as follows: copper 53.5, iron 0.08, sulfate 19.0, carbonate 2.0, water 2.0 – 5.0. This is analyzed according to [51].

5. Compounds and Complexes of Minor Importance

5.1. Copper Compounds

Copper(I) acetate [*598-54-9*], $CuCH_3COO$, M_r 122.6, is obtained as white crystals which are stable when dry but decompose on exposure to water. The product is obtained by reducing an ammoniacal solution of copper(II) acetate; on acidification with acetic acid, the crystals precipitate. Ammoniacal solutions of copper(I) acetate are used commercially to absorb olefins.

Copper(II) acetate monohydrate [*6046-93-1*], neutral verdigris, $Cu(CH_3COO)_2 \cdot H_2O$, M_r 199.65, *mp* 115 °C, d_4^{25} 1.88, decomposes at 240 °C; it forms dark green, monoclinic crystals; its solubility in water at 25 °C is 6.8 g/100 g solution; the compound is slightly soluble in methanol, diethyl ether, and acetone.

Copper(II) acetate monohydrate is produced by the reaction of copper(II) carbonate or copper(II) hydroxide with a solution of acetic acid or by the reaction of copper(II) oxide with hot dilute acetic acid. Alternatively, the material can be made by refluxing aqueous acetic acid in the presence of copper metal and air. The technical product is generally 99 % pure.

Copper(II) acetate monohydrate is used in textile dyeing and as a ceramic pigment. It is used as a fungicide, as a precursor in the production of Paris green [copper(II) acetoarsenite], and as a polymerization catalyst in organic reactions.

Copper(II) acetate, basic [*52503-63-6*], $Cu(CH_3COO)_2 \cdot CuO \cdot 6H_2O$ (variable), M_r 369.26, exists as blue to green salts, depending on the amount of water of hydration. Blue verdigris has the above formula, while green verdigris has fewer molecules of water of hydration. The salts are slightly soluble in water or ethanol, and soluble in dilute mineral acid or aqueous ammonia.

The basic salts are produced by neutralizing copper(II) acetate solutions. They can also be prepared by refluxing acetic acid over copper in the presence of air until the basic salt precipitates.

The basic copper(II) acetates are used as precursors in the manufacture of Paris green [copper(II) acetoarsenite] and as fungicides. They are used as pigments in oil- and water-based paints and in textile dyeing.

Copper(II) acetoarsenite [*12002-03-8*], (acetato)trimetaarsenitodicopper(II), $Cu(CH_3COO)_2 \cdot 3Cu(AsO_2)_2$ (variable), M_r 1013.77, also known as Paris green, is an emerald green, poisonous powder. It is virtually insoluble in water and ethanol but dissolves in dilute mineral acids and aqueous ammonia. Copper(II) acetoarsenite is primarily made by the reaction of a solution of copper(II) sulfate with arsenic(III) oxide, sodium carbonate, and acetic acid

$$4\,CuSO_4 + 3\,As_2O_3 + 4\,Na_2CO_3 + 2\,CH_3COOH \longrightarrow Cu(CH_3COO)_2 \cdot 3\,Cu(AsO_2)_2 + 4\,Na_2SO_4 + H_2O + 4\,CO_2$$

or by the reaction of copper(II) oxide with a hot solution of acetic acid and arsenic(III) oxide. A solution of copper(II) acetate or a suspension of basic copper(II) acetate can also react with arsenic(III) oxide. The product is used as an insecticide, in the preservation of wood, and as an antifouling pigment.

Copper(II) arsenate [*7778-41-8*], $Cu_3(AsO_4)_2 \cdot 4H_2O$ (variable), M_r 540.52, is a blue-green to blue insoluble powder. It is most often prepared by reaction of copper(II) sulfate solutions with arsenic(V) oxide and sodium hydroxide. Copper(II) arsenate is used as an insecticide, fungicide, rodenticide, wood preservative, and antifouling pigment.

Copper(II) arsenite, $CuHAsO_3$ (variable), M_r 187.47, Scheele's green, an insoluble green powder, is prepared by the reaction of a copper(II) sulfate solution with arsenic(III) oxide and sodium hydroxide and is used as pigment and insecticide.

Copper(I) bromide [*7787-70-4*], CuBr, M_r 143.45, *mp* 504 °C, *bp* 1345 °C, d_4^{25} 4.72, forms white cubic crystals that slowly decompose on exposure to light or to moist air; it is soluble in hydrochloric and hydrobromic acids and in aqueous ammonia, but very slightly soluble in water. This compound is prepared pyrometallurgically [see copper(I) chloride, Section 4.1] or by reducing a copper(II) sulfate solution in the presence of sodium bromide, usually with sulfur dioxide or metallic copper. Copper(I) bromide is used as a polymerization catalyst for organic reactions.

Copper(II) bromide [*7789-45-9*], $CuBr_2$, M_r 223.36, *mp* 498 °C, d_4^{25} 4.77, crystallizes from warm solution as black, deliquescent, monoclinic crystals. Below 29 °C, the green tetrahydrate, $CuBr_2 \cdot 4\,H_2O$, results. The anhydrous product is very soluble in water (55.7 g/100 g solution) and soluble in ethanol and acetone. It is insoluble in diethyl ether, benzene, or concentrated sulfuric acid. Copper(II) bromide is most conveniently prepared by dissolving copper(II) oxide in hydrobromic acid; it can also be prepared by the direct action of bromine water on metallic copper. Copper(II) bromide is used as a brominating reagent and catalyst in organic synthesis and as an intensifier in photography.

Copper(II) chromate(VI) [*13548-42-0*], $CuCrO_4$, M_r 179.55, is obtained as reddish brown crystals. Numerous insoluble basic salts can be formed from solutions. Neutral copper(II) chromate is prepared by direct heating of a mixture of copper(II) oxide and chromium(VI) oxide. It decomposes around 400 °C, with the formation of copper(II) chromate(III). Copper(II) chromate(VI) is used in wood preservation and in the weatherproofing of textiles.

Copper(II) chromate(III) [*12018-10-9*], $CuCr_2O_4$, M_r 231.56, forms black, tetragonal crystals which are insoluble in water. It is prepared by heating neutral copper(II) chromate(VI) to 400 °C. Copper(II) chromate(III) is used as a hydrogenation catalyst.

Copper(I) cyanide [*544-92-3*], CuCN, M_r 89.56, *mp* 474 °C (in nitrogen), d_4^{25} 2.92, is usually a white to cream-colored powder, which is practically insoluble in water, cold dilute acids, and ethanol, but dissolves in ammonia and alkali cyanide solutions with the formation of complexes. Copper(I) cyanide is produced by the addition of an alkali cyanide and sodium hydrogensulfite to a solution of copper(II) sulfate:

$$2\,CuSO_4 + 2\,NaCN + NaHSO_3 + H_2O \longrightarrow 2\,CuCN + 3\,NaHSO_4$$

Copper(I) cyanide is very poisonous and must be handled cautiously. It is used in electroplating and in organic reactions as a polymerization catalyst or as a means of introducing the cyanide moiety. Copper(I) cyanide has also been used as an antifouling pigment for marine paints and is an active fungicide and insecticide.

Copper(II) formate [*544-19-4*], $Cu(HCOO)_2$, M_r 153.58, *mp* ca. 200 °C (decomp.), d_4^{25} 1.831, is soluble in water and slightly soluble in ethanol. The reaction of copper(II) oxide, carbonate, or hydroxide with formic acid is used to prepare the product. The most common commercial form, a royal blue material, is prepared by crystallization from water at 75 – 85 °C. A metastable dihydrate is produced by crystallization at 50 – 60 °C. Copper(II) formate tetrahydrate is prepared by crystallization from cool solutions. Copper(II) formate is used to prevent bacterial and mildew growth in cellulosic materials.

Copper(II) gluconate [*527-09-3*], $Cu(C_6H_{11}O_7)_2$, M_r 453.85, forms light blue to blue-green crystals from water; it is soluble in water and slightly soluble in ethanol. Copper(II) gluconate is prepared by the reaction of gluconic acid solutions with basic copper(II) carbonates or copper(II) hydroxide. It is used as a dietary supplement for copper deficiency and in mouth deodorants or breath fresheners.

Copper(I) iodide [*7681-65-4*], CuI, M_r 190.49, *mp* 605 °C, *bp* 1290 °C, d_4^{25} 5.62, occurs in nature as the mineral marshite, white to reddish brown cubic crystals. It is virtually insoluble in water but dissolves in ammonia solution, alkali iodide and cyanide solutions, and dilute hydrochloric acid. Copper(I) iodide is manufactured pyrometallurgically by the reaction of hot copper with iodine vapor. Alternatively, copper(II) salt solutions are reacted with alkali iodides to precipitate copper(I) iodide. Copper(I)

iodide is used as a heat and light stabilizer in polymers, photographic emulsions, and light-sensitive papers, and in oil drilling to aid in corrosion inhibition in highly acid environments. It is also used as a feed additive, in cloud seeding, and as a double salt with mercury(II) iodide as a temperature indicator.

Copper(II) nitrate trihydrate [*10031-43-3*], $Cu(NO_3)_2 \cdot 3\,H_2O$, M_r 241.59, *mp* 114.5 °C, d_4^{25} 2.32, is a blue, deliquescent salt that crystallizes as rhombic plates. It is very soluble in water (77.4 g/100 g solution) and ethanol. When crystallized from solution below the transition point (26.4 °C), the hexahydrate is produced, $Cu(NO_3)_2 \cdot 6\,H_2O$ [*13478-38-1*], M_r 295.64, *mp* 26.4 °C (with loss of 3 mol of water of hydration), d_4^{24} 2.07, blue, deliquescent, prismatic crystals. The anhydrous nitrate is not produced by heating the hydrates; instead, decomposition to the basic copper(II) nitrate [*12158-75-7*], $Cu_2(NO_3)(OH)_3$, begins around 80 °C. Conversion to copper(II) oxide is complete at 180 °C. Copper(II) nitrates are obtained by dissolving copper(II) oxide, basic copper(II) carbonate, or copper(II) hydroxide in nitric acid solution. The various hydrate crystals obtained depend on the conditions of crystallization. Basic copper(II) nitrate can be precipitated directly from solution by neutralization. Copper(II) nitrate salts are often produced by dissolving copper metal in nitric acid solution. The reaction is vigorous, and oxides of nitrogen are evolved:

$$Cu + 4\,HNO_3 \longrightarrow Cu(NO_3)_2 + 2\,H_2O + 2\,NO_2$$

$$3\,Cu + 8\,HNO_3 \longrightarrow 3\,Cu(NO_3)_2 + 4\,H_2O + 2\,NO$$

The second reaction is favored by a lower temperature and dilute acid. Anhydrous copper(II) nitrate [*3251-23-8*] can be produced in ethyl acetate:

$$Cu + N_2O_4 \longrightarrow Cu(NO_3)_2 \cdot N_2O_4 \xrightarrow{90\,°C} Cu(NO_3)_2$$

It is not available commercially.

The hydrates of copper(II) nitrate are used in the textile industry as oxidants and mordants in dyeing. They are used to prepare a copper(II) oxide of high surface area, which is useful as a catalyst in numerous organic reactions. The nitrate salts are used as colorants in ceramics, in the preparation of light-sensitive papers, and in the burnishing of iron, as well as the browning of zinc and brightening of aluminum. They are also used in pyrotechnics and as an oxidative component in solid rocket fuels.

Copper(II) oxalate [*814-91-5*], CuC_2O_4, M_r 151.56, is a blue-white powder, which is very slightly soluble in water. Copper(II) oxalate is prepared by precipitation from a mixture of a copper(II) salt and sodium oxalate solution. The product is used as a stabilizer for acetylated polyformaldehyde and as a catalyst in organic reactions.

Copper(II) phosphate trihydrate [*7798-23-4*], $Cu_3(PO_4)_2 \cdot 3\,H_2O$, M_r 434.61, is a light blue powder which is insoluble in cold water, slightly soluble in hot water, and soluble in ammonia solution and mineral acids. This compound is prepared by reaction of copper(II) sulfate solution with soluble alkali phosphates; it precipitates as a voluminous, almost gelatinous, product. Copper(II) phosphate trihydrate is used as a fungicide and corrosion inhibitor.

Copper(II) diphosphate hydrate [*10102-90-6*], $Cu_2P_2O_7 \cdot x\,H_2O$ (variable), has the following typical analysis: Cu 33 – 36 %, P_2O_7 45 – 49 %. Copper(II) pyrophosphate is a light blue powder which is insoluble in water, but soluble in solutions containing an excess of diphosphate. It is prepared by the precipitation reaction of solutions of copper(II) sulfate and alkali diphosphate. Solutions are used for plating copper on plastics, aluminum, and zinc.

Copper(II) selenide [*1317-41-5*], CuSe, M_r 142.5, *mp* not defined, d_4^{25} 6.0, decomposes at dull red heat; it is insoluble in water but dissolves in hydrochloric acid with evolution of H_2Se. Copper(II) selenide is prepared by reducing copper(II) selenite with hydrazine. It is used as a catalyst in the digestion of organic chemicals by the Kjeldahl method.

Copper(II) soaps are water-insoluble copper salts of long-chain fatty acids. They are usually sold as 6 – 10 % copper solutions in a kerosene diluent. The copper(II) soaps are commonly prepared by direct reaction of the fatty acid with copper(II) hydroxide or basic copper(II) carbonate in an organic diluent, or by precipitation from aqueous media when copper(II)

sulfate solution is mixed with the sodium salt of the respective fatty acid. The common commercially available soaps, concentrations, and uses follow.

Copper (II) naphthenate [*1338-02-9*] contains 8 % copper and is used as a mildewcide in textiles, woods, and paints, and to prevent barnacle growth on ship bottoms.

Copper (II) oleate (9-octadecenoate) [*1120-44-1*], M_r 626.43, contains between 6 and 9 % copper, and is used as a combustion improver in fuel oils, as an emulsifier and dispersant, and as an antifouling coating for fish nets and lines.

Copper (II) stearate (octadecanoate) [*660-60-6*], M_r 630.46, contains 10 % copper, and is used in antifouling paints and in the preservation of wood and textiles.

Copper(I) sulfide [*22205-45-4*], Cu_2S, M_r 159.15, *mp* 1100 °C, d_4^{25} 5.6, occurs in nature as the mineral chalcocite [*21112-20-9*], blue to gray rhombic crystals, also known as copper glance. It has a lustrous metallic look. Copper(I) sulfide is virtually insoluble in water, but is soluble with decomposition in nitric acid and concentrated sulfuric acid, and soluble in alkali cyanide solution through complex formation. It is decomposed to copper(II) oxide, copper(II) sulfate, and sulfur dioxide by heating in air, and to copper(II) sulfide and copper by heating in the absence of air. Copper(I) sulfide is prepared by heating copper and sulfur in a hydrogen atmosphere or by precipitation with hydrogen sulfide from an ammoniacal copper(II) salt solution. It is used in luminous paints, lubricants, solar cells, thermoelements, and semiconductors.

Copper(II) sulfide [*1317-40-4*], CuS, M_r 95.60, d_4^{25} 4.6, decomposes at 220 °C and occurs in nature as the mineral covellite [*19138-68-2*], as blue-black hexagonal or monoclinic crystals. It is virtually insoluble in water, but soluble in alkali cyanides and in ammonia solution with complex ion formation. This compound is decomposed by hot nitric acid. It is stable in dry air, but is slowly oxidized to copper(II) sulfate in moist air. Copper(II) sulfide can be prepared by melting an excess of sulfur with copper(I) sulfide or by precipitation with hydrogen sulfide from a solution of anhydrous copper(II) chloride in anhydrous ethanol. It is used in the dye industry for the preparation of aniline black dyes and as an antifouling pigment.

Copper(II) tetrafluoroborate [*38465-60-0*], $Cu(BF_4)_2$, M_r 237.15, is prepared commercially by the neutralization of tetrafluoroboric acid with copper(II) hydroxide or basic copper(II) carbonate. It is generally produced as a concentrated solution and is used in the production of printed circuits and in copper plating.

Copper(I) thiocyanate [*1111-67-7*], CuSCN, M_r 121.62, *mp* 1084 °C (under nitrogen), d_4^{25} 2.84, is a white to yellow amorphous powder, which is very slightly soluble in water and dilute mineral acids, and soluble in ammonia solution, alkali thiocyanate solutions, and diethyl ether. It is stable to dry air but slowly decomposes in moist air. The material is prepared by reacting a copper(I) chloride solution with an alkali metal thiocyanate at 80 – 90 °C. The recovered product is dried under nitrogen. Copper(I) thiocyanate is used as an antifouling pigment.

5.2. Copper Complexes

Copper(I) and copper(II) ions form many stable complexes with halides, amines, azo compounds, cyanides, and other complexing media. This, in part, accounts for the fact that more X-ray crystal structures have been determined for copper complexes than for any other first-row transition metal ion. Many of these complexes are of great commercial significance. The dissociation constants for a number of copper complexes are given in Table 8 (see next page).

Copper Ammine Complexes. Copper(II) salts form complexes of the type $[Cu(NH_3)_n]^{2+}$ where $n = 1 - 5$. The pentaammine complex is favored only in concentrated ammonia solution (Table 8). The hexaammine complex is formed only in anhydrous ammonia. The tetraammine complex of copper(II) is favored at low ammonia concentrations. For the copper(I) complexes of ammonia, the diammine complex is favored. Tetraammine copper(II) hydroxide, $[Cu(NH_3)_4](OH)_2$, Schweitzer's reagent, is used in the dissolution of cellulose and in the production of rayon (→ Cellulose). Copper(I)

Table 8. Dissociation constants of copper(I) and copper(II) complexes (p$K = -\log K$)

Complex ion	Dissociation products		pK
$[CuCl_3]^-$	CuCl	$+2\,Cl^-$	−2.0
$[CuCl_2]^-$	Cu^+	$+2\,Cl^-$	4.7
$[CuBr_2]^-$	CuBr	$+Br^-$	−3.3 to −2.3
$[CuBr_2]^-$	Cu^+	$+2\,Br^-$	5 to 6
$[Cu(CN)_3]^{2-}$	$[Cu(CN)_2]^-$	$+CN^-$	11.3
$[Cu(CN)_2]^-$	Cu^+	$+2\,CN^-$	16
$[Cu(NH_3)_2]^+$	Cu^+	$+2\,NH_3$	10.8
$[Cu(NH_3)]^{2+}$	Cu^{2+}	$+NH_3$	4.1
$[Cu(NH_3)_2]^{2+}$	Cu^{2+}	$+2\,NH_3$	3.5
$[Cu(NH_3)_3]^{2+}$	Cu^{2+}	$+3\,NH_3$	2.9
$[Cu(NH_3)_4]^{2+}$	Cu^{2+}	$+4\,NH_3$	2.1
$[Cu(NH_3)_5]^{2+}$	Cu^{2+}	$+5\,NH_3$	−0.5
$[CuCl_4]^{2-}$	$[CuCl_3]^-$	$+Cl^-$	0.01
$[CuCl_3]^-$	$CuCl_2$	$+Cl^-$	0.06
$CuCl_2$	$CuCl^+$	$+Cl^-$	0.4
$CuCl^+$	Cu^{2+}	$+Cl^-$	1
$[Cu(OH)_4]^{2-}$	$[Cu(OH)_3]^-$	$+OH^-$	0.9
$[Cu(OH)_3]^-$	$Cu(OH)_2$	$+OH^-$	−5

diammine salt solutions are used in the absorption of olefins and carbon monoxide. Many copper circuit boards are etched with ammoniacal ammonium salt solutions; copper ammine solutions, which can be used in the production of copper compounds, are byproducts of this process.

Copper Chloride Complexes. Copper(I) and copper(II) ions form complexes with hydrochloric acid or soluble metal chlorides. Dilute solutions of copper(II) chloride are blue. As the chloride concentration increases, the color of the solution shifts toward green, intensifying as the concentration of the distorted tetrahedral $[CuCl_4]^{2-}$ ion increases. Copper(II) compounds have been isolated that contain either the $[CuCl_4]^{2-}$ anion or the $[CuCl_3]^-$ anion, e.g., $CsCuCl_4$ and $KCuCl_3$, respectively.

The insoluble copper(I) chloride can be solubilized by chloride-containing solutions, with the formation of the $[CuCl_2]^-$ ion. The benzene-insoluble copper(I) chloride dissolves readily in the presence of anhydrous aluminum chloride, with formation of the $Al[CuCl_4]$ complex. In acetonitrile, copper(I) chloride is solubilized with the formation of the isolable $[Cu(CH_3CN)_4]Cl$ complex.

Copper(I) Cyanide Complexes. Alkali cyanides readily dissolve copper(I) cyanide, with the formation of $[Cu(CN)_2]^-$ and $[Cu(CN)_3]^{2-}$ complexes. Solutions of the complexes are of great importance in the electroplating industry because of their versatility. From saturated copper and sodium cyanide baths, crystals of the double salt $Na_2Cu(CN)_3 \cdot 2\,H_2O$ can be obtained readily.

Other Copper Complexes of Industrial Significance. Solvent extraction of copper(II) ions relies on the ability of copper to form complexes and to break those complexes as a function of pH [110], [126], [127]. The most common reagents used commercially are substituted salicylaldoximes, 1,8-hydroxyquinolines, and α-hydroxyoximes.

Copper(II) is solubilized in alkaline media by complex formation with tartrates for use as Fehling's solution, which is utilized in the analysis of reducing sugars. Copper(II) bis(1,8-dihydroxyquinoline) is used as a textile fungicide and as a pigment. Copper phthalocyanines [128], [129] are exceptionally stable blue and green pigments, as are the azo dye complexes of copper (→ Azo Dyes; → Phthalocyanines).

6. Copper Reclamation

The reclamation or recycling of copper wastes and byproducts is environmentally imperative and, in many cases, economically sound. Better technologies have been developed to produce useful materials from wastes and byproducts,

many of which are now considered hazardous wastes. The establishment of the Resource Conservation and Recovery Act (RCRA) by the EPA defined procedures to assure proper disposal or reclamation of hazardous wastes [130]. However, no distinction is made between waste buried in an approved landfill and waste recovered as useful products. Unfortunately, in many cases this encourages the burial of recyclable waste materials.

The largest sources of reclaimable byproduct copper are the electronics and plating industries, as well as spent electrowinning baths [113]. Electrowinning baths are most often crystallized (Section 4.4.1) or precipitated as tribasic copper(II) sulfate for use in agriculture.

In the manufacture of circuit boards, a copper laminate is selectively dissolved (etched). This dissolution process yields the desired circuit board and a byproduct copper solution, the spent etchant. The earliest etching solutions used iron(III) chloride – hydrogen chloride or chromium trioxide – sulfuric acid solutions which were difficult to recycle. Later, the sulfuric acid etchants that used hydrogen peroxide [131], [132] or persulfate [133–135] as oxidants were developed. Recycling of the copper is achieved through crystallization, precipitation [135], ion exchange [136], or cementation [137], [138]. Alkaline etchants utilized a mixture of ammonia and ammonium sulfate with persulfate as the oxidant [139] or a mixture of ammonia and ammonium chloride with chlorite as the oxidant [140]. The primary etchants used today are the ammonia – ammonium chloride system with air as the oxidant and the hydrochloric acid system with stabilized hydrogen peroxide as the oxidant [141].

Copper is recovered from the acid chloride etchants (1) by neutralization and precipitation of copper(II) oxychloride or copper(II) oxide [42]; (2) by reduction with sodium hydrogensulfite, for example, to precipitate copper(I) chloride which can then be converted to copper(I) oxide by sodium hydroxide treatment [142]; or (3) by cementation with scrap iron [143]. From the alkaline etchants, copper is recovered (1) by distillation to strip ammonia and precipitate copper(II) oxide [144]; (2) by addition of base to precipitate copper(II) hydroxide, followed by steam stripping of the ammonia [145]; (3) by reduction to copper with formaldehyde [146] or $Na_2S_2O_4$ [147]; or (4) by electrolysis [148].

One of the more elegant methods for the recovery of copper from ammonia – ammonium chloride etchants utilizes solvent extraction [149] (Fig. 8). Not only is the copper recovered, but the etchant is simultaneously regenerated:

$$[Cu(NH_3)_4]Cl_2\,(aq) + 2\,RH \longrightarrow \underbrace{CuR_2}_{\text{Fresh etchant}} + 2\,NH_3\,(aq) + 2\,NH_4Cl\,(aq)$$

$$CuR_2 + H_2SO_4\,(aq) \longrightarrow 2\,RH + \underbrace{CuSO_4}_{\text{Reclaimed copper}}\,(aq)$$

where R is an α-hydroxyoxime as shown in page 14.

The copper can be further reclaimed by crystallization or electrowinning.

7. Copper and the Environment

The reclamation of copper byproducts and wastes and the regulation of plant effluents and sanitary waters have resulted in lower indiscriminate release of copper into natural waters [150]. Where large quantities of copper in high concentration exist (see Chap. 6), recovery of the copper can, in many cases, be economical. Regulations have been established to control or limit altogether the introduction of copper into waters [151–155]. The Federal Water Pollution Control Act Amendments of 1972 set up a comprehensive program to "restore and maintain the chemical, physical, and biological integrity of the nation's waters" [151].

Limitations of copper in drinking water have also been established: the World Health Organization recommends 0.05 – 1.5 mg/L [156]. No specific drinking water standards for copper have been established by the Environmental Protection Agency [157].

A variety of technologies presently exist for the removal of copper from wastewaters and drinking water [158], [159]. The most common treatment methods include direct precipitation [151–153], [160–163] or electrolysis [164], [165].

Although copper is toxic in exceedingly low concentrations to certain lower life forms, notably fungi and algae, it is a necessary con-

stituent of higher plants and animals (see, however, Chap. 9). Copper plays a necessary role as an oxidation catalyst and oxygen carrier, probably second only to iron in importance [166]. Copper aids plants in photosynthesis and other oxidative processes. In higher animals, it is responsible for oxidative processes and is present in many proteins such as phenolase, hemocyanin, galactose oxidase, superoxide dismutase, ceruloplasmin, tyrosinase, monoamine oxidase, and dopamine β-hydroxylase [167], [168].

Copper compounds are regularly applied for their nutrient value to agricultural crops in European countries [169–171]. In the United States, more emphasis is now being placed on the value of copper as a nutritional feed additive [169], [172], [173]: it increases the rate of gain and feed efficiencies of the animals. The increased use of copper as a feed additive has caused concern about the environmental impact of high levels of copper in manure [174], [175]. The approved maximum total copper content in animal feeds for Western European countries is shown in Table 9 [169].

Table 9. Maximum copper levels in Western European animal feeds

Use	Total copper, mg/kg
Fattening pigs, up to 16 weeks	175
Fattening pigs, 17th week to 6th months	100
Fattening pigs, over 6 months	50
Breeding pigs	50
Calves, fed milk-based products	30
Calves, other feeds	50
Sheep	20
Other animals	50

The largest single application of copper compounds is as an agricultural fungicide (see Chap. 8). Although copper is a necessary constituent of higher plants and animals, it is highly toxic to certain fungi. In human medicine, the importance of copper as a nutrient in proper development and growth is receiving increased study [167], [176]. Also, copper is being used in the production of new copper antibiotics and copper anti-inflammatory drugs [176]. The recommended daily requirement of copper is as follows [176]:

Humans	2.5 – 5.0 mg
Cattle	50 – 70 mg
Horses	50 – 60 mg
Sheep	10 – 15 mg
Swine	10 – 20 mg

8. Economic Aspects

The world's production of copper compounds represents less than 2 % of the total production of primary metal [65]. In 1974, 7.65×10^6 t of primary copper was produced, with 1.3 % (100 000 t) used in the production of copper compounds. Of these 100 000 t, 80 % is used to prepare copper(II) sulfate pentahydrate.

Historically, the United States and Italy have led the world in producing copper sulfate pentahydrate (Fig. 9) [65]. The U.S. production and valuation of copper sulfate pentahydrate are given in Table 10 [177].

Figure 9. Production of copper(II) sulfate pentahydrate in Italy and the United States (1950 – 1976)

Table 10. Production and valuation of copper(II) sulfate pentahydrate in the United States

Year	Production		Price of copper(II)
	Quantity, t	Copper content, t	sulfate pentahydrate, U.S. $/kg
1978	31 880	8551	1.04
1979	35 005	9286	1.18
1980	31.010	8445	1.23
1981	35 640	9413	1.14
1982	32 230	8385	1.08

Total	70 305	76.4	12.1	11.4

According to estimates about 70 % (70 000 t) of the total world's production of copper compounds is used in agriculture [169]. Table 11 gives a breakdown by region, country, and use. Copper sulfate pentahydrate can be blended directly with feed or fertilizers for animal feeds or crop nutrients, respectively. For application as a foliar fungicide, it must be rendered insoluble to prevent it from being easily washed off the leaf. The first copper fungicide on the market was Bordeaux mixture (1882), a combination of lime and copper sulfate [178]. The inherent phytotoxicity of Bordeaux mixture led to the development of the "fixed coppers" in the 1920s and 1930s. The fixed coppers are grouped into four categories: (1) basic sulfates, (2) basic chlorides, (3) oxides, and (4) miscellaneous – silicates, phosphates, etc. [179], [180]. To enhance their performance, the fixed coppers are usually blended with wetting agents, dispersants, sticking agents, and diluents. Since better coverage and enhanced efficacy are obtained with smaller particles, the basic coppers are usually ground before packaging [181]. Table 12 (see next page) gives a partial list of available fixed copper fungicides.

9. Toxicology and Occupational Health

Copper is an essential trace element in humans. In larger quantities it can be lethal. The salts are usually considered to be more toxic than the metal. The acute oral toxicity in humans, LD_{Lo}, is about 100 mg/kg; however, recovery has occurred after ingestion of up to 600 mg/kg. The symptoms of copper poisoning include nausea, vomiting, gastric disturbances, apathy, anemia, cramps, convulsions, coma, and death.

Many reported cases of illness were once attributed to chronic copper poisoning, but they are

Table 12. Commercially available fixed coppers

Manufacturer/representative	Trade name	Active ingredient	Cu content, %
BASF	BASF-Grünkupfer	copper oxychloride	45
	Kauritil	copper oxychloride	47

Spiess Urania	Funguran	copper oxychloride	45
	Cuprasol	copper oxychloride	50
Tennessee Copper	Tribasic Copper Sulfate	tribasic copper sulfate	53
Wacker	Wacker-Kupferkalk	copper oxychloride	15 – 18

now thought to be caused by impurities in the refining of copper, e.g., lead, arsenic, and selenium [182], [183]. The question of chronic poisoning is still open to debate. Prolonged exposure to copper dust can cause skin irritation and discoloration of skin and hair. Whether pathological changes occur is uncertain, although there is evidence of accumulation of copper in the liver. Attempts to induce chronic copper poisoning in animals have been unsuccessful.

The inhalation of dusts of copper compounds irritates the upper respiratory tract [184], [185]. Ulceration and perforation of the nasal septum have occurred. Workers exposed to dusts of copper salts complained of metallic tastes and irritation of the oral and nasal mucosa. Smokers complained of an intense sweet taste during inhalation of the smoke. Long-term exposure to copper-containing dust has resulted in atrophic changes in the mucous membranes. Mild nasal discomfort was noted in workplace concentrations as low as 0.08 mg/m^3. A very small fraction of the workers exhibited allergic skin reactions from exposure to copper-containing dust [186], [187].

Copper compounds embedded in the eye produce a pronounced foreign body reaction with discoloration of the ocular tissue. Conjunctivitis, ulceration, and turbidity have been reported [188], [189].

The workplace standard for copper dust concentration in air, MAK and TLV, is 1 mg/m^3 [190–192]. Copper fume standards are 0.2 mg/m^3 [190] and 0.1 mg/m^3 [191], [192]. A number of reviews and books of a more specific nature report detailed animal and workplace studies [193–197].

1. Introduction

Since the early 1990s combinatorial chemistry has become a major focus of research activity for pharmaceutical, agrochemical, and biotechnology companies.

The ongoing introduction of combinatorial chemistry seems to result in a fundamental change in the way how the drug discovery process for new or improved therapeutics and agrochemicals is carried out. The key issues of combinatorial chemistry are lead finding and lead optimization. A *lead* is a compound with an appreciable degree of affinity for the biological target of interest. Conventionally, drug development involved the individual synthesis and biological evaluation of hundreds to thousands of organic compounds in an attempt to enhance the biological activity, selectivity and bioavailability, while at the same time decreasing its toxicity

Figure 1. Drug discovery process to new or improved drug candidates in the R & D laboratories of pharmaceutical and agrochemical companies

(see Fig. 1). On an average, such a drug discovery process takes 6.5 years before a suitable drug candidate is found.

Combinatorial synthesis as a high-throughput method enables to rapidly produce hundred to thousand times more compounds than conventional serial organic synthesis in an efficient manner. This in conjunction with high-throughput screening (→ High-Throughput Screening) and the increasing number of new biological targets is expected to accelerate the process for discovering new and improved drug candidates [1–11]. Thus, combinatorial chemistry has attracted attention of companies as a means of cutting the time and high costs associated with the serial drug discovery process.

The underlying concepts used in combinatorial chemistry in the synthesis of organic compounds have their origin in the field of peptide chemistry. Pioneers such as Geysen (multipin method) [12], [13] and Houghten (teabag method) [14] developed various methods for multiple (parallel) synthesis of peptides in 1984 – 1985, based on the techniques of solid-phase peptide synthesis according to Merrifield [15] (→ Peptide Synthesis, Chap. 5.2.) that was presented first in 1963. Further progress was achieved in this field, among others by Frank (spot synthesis) [16] and Fodor (VLSIPS method) [17], [18]. However, combinatorial synthesis of peptides in the literal sense was made possible by the work of Furka (split – pool method) [19–22] in 1988, and this can be regarded as the "birth" of combinatorial chemistry. These studies have clearly demonstrated the power of combinatorial synthesis in medical chemistry. But peptides and oligonucleotides generally have low bioavailability and are rapidly proteolytically degraded and therefore their utility as therapeutic agents is often limited [23]. Due to the more favorable pharmacokinetic properties of many organic compounds (generally with a molecular mass < 750), termed small molecules, combinatorial synthesis of small molecules has rapidly become of particular importance in organic chemistry.

This overview will focus on the methods employed in design, synthesis, and screening of combinatorial libraries of small molecules and

on the interrelationship between these methods. In its optimal form combinatorial chemistry involves robotic instruments for the automated synthesis as well as for the screening of compounds, and computational methods for the library design. Furthermore, industrial case studies will be given in the field of drug discovery and other application areas such as material science and catalysis will be described.

Figure 2. A) In general, in a conventional synthesis one starting material A reacts with one reagent B resulting in one product AB; B) In a combinatorial synthesis different building blocks of type A ($A_1 - A_n$) are treated simultaneously with different building blocks of type B ($B_1 - B_n$) according to combinatorial principles, i.e., each starting material A reacts separately with all reagents B resulting in a combinatorial library A_{1-n} B_{1-n}

2. Concept of Combinatorial Chemistry

The concept of combinatorial chemistry is to prepare a large number of different compounds at the same time – instead of synthesizing compound one by one, as is done conventionally – and then to identify the most promising compound for further development by high-throughput screening.

The salient feature of combinatorial synthesis is that different compounds are generated simultaneously under identical reaction conditions in a systematic manner so that ideally the products of all possible combinations of a given set of starting materials (termed building blocks) will be obtained at once (see Fig. 2). The collection of these finally synthesized compounds is referred to as a *combinatorial library* (The term "library" is not used consistently in the literature. Often this designation is reserved for compound mixtures, whereas collections of separate single substances are called "arrays".)

The combinatorial libraries can be structurally related by a central core structure, termed scaffold, or by a common backbone, as shown in Figure 3. In both cases the accessible dissimilarity of the compounds depends on the building blocks which are used for the construction of the library.

The size of the combinatorial library ranges from a few tens to many hundreds of thousands compounds. In a multistep combinatorial synthesis, generally required for drug relevant compounds, the total number of all synthesized compounds within the combinatorial library is determined by two factors: the number of building blocks used per reaction and the number of reaction steps, in which a new building block is incorporated. The number of all synthesized compounds $\underline{N}$ is given by the equation $N = b^x$, where b is an equal number of building blocks used in each reaction (1, 2, . . ., x) and x is the number of reaction steps, in which a new building block is introduced. If the number of building blocks for each reaction step varies (e.g., a, b, c in a three-step synthesis), then $N = a \cdot b \cdot c$. Thus, a large compound library will be obtained rapidly from only a few building blocks.

Depending on the synthetic strategy used the created combinatorial library can comprise compound mixtures, or separate, single substances. [The term "combinatorial synthesis" was strictly used only when different building blocks are treated in one reaction vessel, and compound mixtures are thus obtained. Since the boundary becomes blurred, herein syntheses of both libraries of compound mixtures and of separate, single substances are included, as long as the procedure can be described as combinatorial (simultaneous synthesis under identical conditions according to combinatorial principles)]. Combinatorial libraries may consist of compounds free in solution, or linked to a solid phase.

3. Methods and Techniques of Combinatorial Synthesis

3.1. Synthetic Strategies Towards Combinatorial Libraries

3.1.1. Split – Pool Synthesis Towards Combinatorial Libraries

FURKA and coworkers pioneered the split – pool synthesis method [19–22] for the synthesis of

Figure 3. Scaffold-based (A) or backbone-based (B) combinatorial libraries

large peptide libraries in 1988; this approach is termed divide, couple, and recombine synthesis by other workers [24–27].

The split – pool synthesis procedure towards combinatorial libraries, as schematically illustrated in Figure 4, involves the splitting of a quantity of resin beads (a swollen insoluble solid support, see Section 3.2.1.1) into multiple equally sized portions in separate reaction vessels, coupling a single building block to each aliquot and then pooling the resin-bound compounds from all reaction vessels together in one vessel. In this vessel the common steps such as resin washing and deprotection are performed in one batch. By reapportioning the resin-bound compounds into the requisite number of separate reaction vessels the second solid-phase reaction provides compounds that incorporate all of the possible combinations of the two sets of building blocks. These split and pool operations are repeated until the desired combinatorial library has been assembled. Currently this is the most popular method for the synthesis of combinatorial libraries of compound mixtures comprising thousands to hundred thousands of compounds.

Combinatorial libraries resulting from split – pool synthesis are referred to as "one-bead-one-compound" libraries according to Lebl [24–26]. This is based on the fact that due to the nature of splitting and pooling the resin beads, each resin bead in a library contains multiple copies of (ideally) just one single compound. Thus, the library consists of quasi separate compounds as long as they are resin-bound.

A variety of methods have been developed to determine the structure of bioactive compounds within libraries of compound mixtures (see Section 4.2.1).

3.1.1.1. Techniques using Resin Beads

The split – pool protocol is normally carried out on resin beads. Due to the statistical distribution of the solid support at each splitting step

Figure 4. Split – pool synthesis to prepare combinatorial libraries of compound mixtures (Spheres represent resin beads, A, B, C represent the sets of building blocks, borders represent the reaction vessels). In the case of 3 building blocks used in each coupling step, after three stages a total number of 27 different compounds, one on each resin bead, are formed using 9 individual reactions (ignoring deprotection).

the combinatorial synthesis should be carried out with an approximately threefold amount of resin beads (termed *x*-fold, here threefold redundancy), in order to ensure that 95 % of all possible compound members of the combinatorial library are included with a probability greater 99 % [28], [29]. For the commonly used resins (about 100 µm diameter bead), 1 g of the support material corresponds to several million resin beads so that from a statistical point of view, libraries of the order of $> 10^5$ different compounds are possible in practice [28–30]. Depending on the loading capacity of the resin bead, quantities of about 200 pmol (0.1 mg compound, $M_r = 500$) can be obtained per resin bead.

Analytical methods for the quality control of combinatorial libraries comprising resin-bound compound mixtures are described in Section 4.1.

3.1.1.2. Tea-Bag Method

In the so-called tea-bag method, originated by HOUGHTEN and co-workers [14] for multiple

peptide synthesis in 1984, the split – pool protocol occurs batchwise on porous polypropylene mesh packets (termed tea bags) sealed with resin beads for solid-phase synthesis (each tea bag contains resin beads with a different substance). This method offers the advantage that a greater quantity of each compound of the library is available at once (up to 500 µmol), which is sufficient for a complete biological and structural characterization. Furthermore, the structural identity of each synthesized compound can be preserved during the split – pool protocol by labeling the tea bags (see Fig. 5 A).

More recently, NICOLAOU and XIAO [31] as well as MORAN [32] developed a radio frequency encoding system. In practice a glass-encased semiconductor memory microchip capable of receiving, storing, and emitting radio frequency signals [33], [34] is placed in a porous polypropylene capsules along with resin beads. (Glass-encased microchips that are pretuned to emit a unique binary code when pulsed with electromagnetic radiation are widely used to tag and identify laboratory animals via subcutaneous injection.) Taking advantage of the radio frequency encodable microchips each of the capsules (tea bag) can undergo the split – pool protocol in a precise manner, wherein each capsule is radioscanned between solid-phase synthesis rounds and a specific radio frequency signal is recorded on the memory microchip for each reaction step (see Fig. 5 B). In the end, the device can be scanned to record the identity of a compound bound on each batch of resin beads. Depending on the size of the capsule and the resin filling quantities of about 7 – 15 mg compound can be obtained in MicroKan Reactors.

3.1.2. Parallel Synthesis Towards Combinatorial Libraries

Combinatorial libraries can also be prepared by parallel synthesis [35]. Here, compounds are synthesized in parallel using ordered arrays of spatially separated reaction vessels adhering to a traditional "one-vessel-one-compound philosophy" (see Fig. 6). This offers the advantage that each compound, when evaluated for some desired performance (see Section 4.2.2), is substantially "pure" in its local areas, provided that the synthesis has proceeded with high efficiency in each stage. Furthermore, in parallel synthesis the defined location of the compound in the array provides the structure of the compound. A commonly used format for parallel synthesis is the 96-well microtiter plate (standard format in high-throughput screening).

In general, combinatorial libraries comprising hundreds to thousands of compounds are synthesized by parallel synthesis, often in an automated fashion (see Chap. 5). Unlike split – pool synthesis, which requires a solid support, parallel synthesis can be done either on solid phase or in solution.

A number of different solid supports and uniquely designed reaction vessels are adopted for the parallel synthesis of organic compound libraries. The yield of the individual compounds synthesized vary widely from nanomoles to millimoles.

3.1.2.1. Reaction Apparatus using Resin Beads

Various reaction apparatus [36] have been developed for parallel synthesis on the basis of a 96-deep-well polypropylene microtiter plate (e.g., the Flexchem Solid Phase Chemistry System, a modular system of hardware designed for high-throughput parallel synthesis marked by Robbin Scientific Corporation.). The resin beads and reaction solutions are placed into each well of the plate. During the reaction step, the plate is clamped against a Viton (i.e., a fluoroelastomer produced by Du Pont) gasket in order to seal the hole at the bottom of the well. Between reaction steps the reaction solution can be drained and the resin can then be rinsed by removal of the Viton gasket.

In 1993 DEWITT and coworkers described the Diversomer apparatus [37–39], which is one of the first reaction apparatus designed exclusively for the parallel synthesis of small molecules. Pipetting machines dispense reagents and solvents into vials that are located in a custom-made reaction block with 40 positions. The ends of gas dispersion tubes – that contain the resin beads – are placed into the vials allowing the reagents to diffuse into the tubes and contact the solid support. The reaction temperature can be controlled by heating and cooling the reaction block. The apparatus is also enclosed in a

Figure 5. Schematic illustration of labeled polypropylene tea bags (A) and radio-frequency (RF) encoded polypropylene capsules (B)

Figure 6. Parallel synthesis to prepare combinatorial libraries of separate single compounds. (Spheres represent resin beads, A, B, C represent the sets of building blocks, borders represent the reaction vessels.) If 3 building blocks are used in each coupling step, after three stages a total of 27 different compounds are formed, one on each resin bead, with 81 individual reactions being used (ignoring deprotection).

manifold with an injectable gasket employed for reagents and solvent additions so that reactions can be maintained under an inert atmosphere. The final compounds are each obtained in quantities larger than 1 mg.

As reaction vessel for resin beads an array of chromatography tubes or syringes fitted with frits and stoppers can also be used. These can be gently agitated on a shaker table or blood tube rotator during the reaction and the resulting compounds can be filtered using a vacuum manifold.

3.1.2.2. Multipin Technique

In 1984, Geysen and coworkers introduced a method for the parallel synthesis of 96 peptide sequences using spatially dispersed polymeric pins [12], [13]. The design of the commercially available Multipin SPOC (Chiron Mimotopes Pty) is based on a modular 8 × 12 matrix of polyacrylamide- or polystyrene-grafted polypropylene pins [40]. The pins are functionalized with a variety of linkers to allow flexibility in solid phase synthesis. The loading levels per pin can range from about 100 nmol to 50 µmol of (ideally) one compound, permitting quantities up to 25 mg compound ($M_r = 500$) to be prepared. Applications are at present in the area of immunology [40].

The execution of the parallel synthesis of up to 96 single compounds by the multipin method (see Fig. 7) involves pipetting the reactants to each well of a standard 96-well microtiter plate. The pin array is then placed on top of the plate and the resin is allowed to incubate with the reactants to perform the coupling step. The reaction temperature can be raised up to 90 °C by placing the reaction block into an incubator. Following each reaction step, the pin array is removed and treated in batch to wash the solid support. These operations are repeated until the desired combinatorial synthesis is completed. The final compounds are cleaved from the pins into a 96-well microtiter plate.

3.1.2.3. Spatially Addressable Parallel Synthesis on Silica Wafer

A special case of parallel synthesis is the spatially addressable synthesis pioneered by Fodor and coworkers [17], [18] in 1991. Here, each member of the library is synthesized at a specific location on a functionalized silica wafer rather than on resin beads in separate reaction vessels. This approach, based initially upon solid-phase peptide synthesis and semiconductor photolithographic techniques by using photolabile amino protecting groups, allows to synthesize combinatorial libraries containing about 50 000 compounds localized to a 50 µm square site on a silica wafer ("library on a chip").

The key points of this method are illustrated in Figure 8. The photolabile protecting groups on the surface of the silica wafer are selectively cleaved at specified locations by site-specific illumination through a mask using instrumentation initially developed for computer microchip construction (→ Imaging Technology, Chap. 4.3.). The entire surface is then exposed to the first set of building blocks bearing also the photolabile protecting group. The coupling reaction occurs only at the sites that were addressed by light in the preceding step. The substrate is illuminated through another mask for deprotection and coupling with a second building block. The steps of illumination and coupling are repeated to build up the members of the compound library. This technique which comprises light-directed spatially addressable parallel chemistry is referred to as very large-scale immobilized polymer synthesis (VLSIPS). It is mostly applied to oligomeric, peptide, and oligonucleotide synthesis.

Figure 7. Schematic representation of the Multipin-SPOC-based parallel synthesis

In the light-directed synthesis, the pattern of masks and the sequence of building blocks define the final structure of the compounds synthesized. The equipment required for light-directed peptide synthesis includes a commercial peptide synthesizer, a flow cell to hold the substrate

and deliver fluids from the synthesizer, a translation stage to move among the masks all located on the same large-format glass plate (which is held against the synthesis substrate in a "contact" printing mode) and an arc lamp that can deliver collimated long-wavelength UV light to the mask [41], [42].

3.1.3. Reagent Mixture Synthesis Towards Combinatorial Libraries

In the so-called reagent mixture synthetic approach towards combinatorial libraries of compound mixtures, each reaction step of the combinatorial synthesis is carried out with a building block mixture in one reaction vessel [43]. The use of reagent mixtures requires a thorough knowledge of the mechanism and kinetics involved in the specific reactions being carried out. It is important that the relative reaction rates of the incoming reagents are approximately equal and relatively independent of the resin-bound compounds (i.e., equal nucleophilicity, no significant steric hindrance).

Reasonable results can be obtained for the addition of one set of building blocks. Repetitive cycles using this method can result in large deviations from equimolarity in the final compound mixture, some compounds formed to a lesser extent or not at all.

Combinatorial synthesis towards libraries of compound mixtures can be done either on a solid support or in solution. In both cases an effective deconvolution strategy is required to extract structural information from the results of the biological assay (see Section 4.2.1.2.3).

3.2. Synthetic Methodology for Organic Library Construction

In principle, combinatorial synthesis can be performed both in solution and on solid phase. Although chemistry in solution has the advantage of being familiar and well-established as the method of choice in conventional organic synthesis, to date the majority of the compound libraries have been synthesized on solid phases such as resin beads, pins, or silica wafers. This may be attributed to reasons that include easy parallel work-up procedures (filtration); accelerated reactions with higher yields by employing

Figure 8. Schematic representation of spatially addressable parallel synthesis on functionalized silica wafer as described in the text (A) and the masking scheme towards combinatorial libraries of a trimer using the generic building blocks A, B, C (B)

excess of reagents; and amenability to automation. Furthermore, it also facilitates the partitioning of compounds into multiple aliquotes in the case of split – pool synthesis.

3.2.1. Solid-Phase Organic Synthesis

Solid-phase organic synthesis is based mainly on the pioneering work of MERRIFIELD [15] in the field of peptide synthesis in 1963 (→ Peptide Synthesis, Chap. 5.2.), and this was followed in the 1970s by investigations on solid-phase synthesis towards organic compounds by LEZNOFF, CAMPS, FRÉCHET, RAPOPORT and others [44–47].

As illustrated in Figure 9, throughout the solid-phase synthesis the compound under construction is covalently attached to a swollen insoluble solid support (usually a resin bead) by a linker that can be cleaved under specific conditions with an appropriate reagent to give the target compound in solution later on (e.g., for assessment of purity, analytical characterization, or biological evaluation). The reactions can be accelerated and driven to completion by using a relatively large molar excess of reagents resulting in reduced reaction time and higher yields. The support matrix in particular facilitates all steps of a synthesis protocol, such as addition of reagent solutions, agitation, filtration, and washing. Thus, solid-phase synthesis enables full automation, even for multistep synthesis, where the building blocks are added repetitively to build up the desired final compound.

Figure 9. Schematic representation of solid-phase synthesis The sphere represents solid support (usually a resin bead), A and B represent the sets of building blocks, and AB the reaction product

Solid-phase synthesis requires functionalized solid supports and orthogonal chemistry suitable for compound attachment and detachment (orthogonal chemistry means functionalization of a bi-/multifunctional molecule in such a way that only the desired part of the molecule is reacted, leaving the rest of the molecule unaffected), and specialized methods for reaction monitoring in a multistep solid-phase synthesis, including the use of attended orthogonal capping strategies for blocking unreacted substrates. It does not permit the purification of support-bound intermediates. Thus, reactions in solid-phase synthesis must be very selective and efficient. Otherwise, the purification of the final products can present a considerable challenge. The scale of solid phase synthesis is limited and generally restricted by the amount of the solid support and its loading capacity, and the preparation of multimilligram quantities can be cumbersome and expensive for large combinatorial libraries (see Table 1).

Table 1. Comparison of different solid supports

Type of support	Loading capacity	Particle size
Resin beads		
PS[a]-DVB[b] resin	0.8 – 1.2 mmol/g	200 – 400 mesh
PEG[c]-PS[a] resin (TentaGel)	0.2 – 0.3 mmol/g	90 – 130 µm
PEG[c]-PS[a] resin (AgroGel)	0.4 – 0.6 mmol/g	110 µm
High-load resin beads		
PEG[c]-PS[a] resin (TentaGel)	0.4 – 0.6 mmol/g	75 – 110 µm
Macrobeads		
PS[a]-DVB[b] resin	0.8 – 1.2 mmol/g 2 – 5 nmol/bead	160 – 200 µm
PEG[c]-PS[a] resin (TentaGel)	0.25 – 0.35 mmol/g 5 nmol/bead	280 – 320 µm

[a] PS = polystyrene. [b] DVB = divinylbenzene.
[c] PEG = poly(ethylene glycol).

[Example: For a combinatorial library consisting of 10 000 compounds (three-step synthesis at 95 % yield/step) to obtain 50 mg of each compound (M_r = 500) on a PS – DVB resin with a typical loading capacity of 1 mmol/g 1.166 kg solid support is required, i.e., ca. $ 2500 for solid support or ca. $ 6 per compound including chemicals, solvents and disposals.]

3.2.1.1. Solid Support, Linker, and Cleavage Strategies

At present, in combinatorial synthesis of organic compounds two types of polymeric solid support are most commonly used, which are commercially available functionalized with different linkers.

Polystyrene resin cross-linked with 1 – 2 % divinylbenzene (PS – DVB resin, Merrifield resin) is advantageous because of its low price, its high

loading level (up to 2 mmol reactive groups per gram), and its relatively high mechanical stability. One major limitation of the polystyrene resin is that the resin beads are not well solvated in protic solvents, resulting in poor accessibility of reaction sites and thus diminished reaction rate.

Polystyrene – poly(ethylene glycol) copolymers (PEG – PS resin) are obtained by grafting polyoxyethylene chains of controlled lengths onto cross-linked polystyrene-based resin. These polymers are sold, e.g., under the name TentaGel (commercially available from Rapp Polymere, loading capacity in the range of 0.2 – 0.3 mmol/g resin) [48–50] and ArgoGel (commercially available from Argonaut Technologies Inc, loading capacity in the range of 0.4 – 0.5 mmol/g). PEG – PS resins swell extensively in a wide range of solvents and are suitable for some on-bead bioassays (see Section 4.2.1.1), in contrast to PS resins. Disadvantages of PEG – PS relative to PS resins include much higher costs, reduced loading levels, and rather low mechanical stability (stirring or vigorous shaking results in significant loss of resin).

Both resins withstand a wide range of reaction conditions and reagents. New solid supports are being developed to improve the uniformity in size and loading, swelling and mechanical stability properties.

Most linkers are acid or base labile. Since the majority of them originate from peptide synthesis, the reactants are often bound to the support by an ester or amide bond and give carboxylic acids and amides or alcohols or amines after cleavage. A variety of new linkers for combinatorial chemistry is based upon the great wealth of knowledge regarding protection of functional groups. This includes (1) multifunctional linkers which enable the release of different functional groups, depending on the reagent used for cleavage from the linkers and (2) traceless linkers which allow the release of the target compound from the linker without formation of additional functionality, e.g., by the use of cyclization reactions or silicon-based linkers.

An area of special interest are multiple cleavable linkers [51], to release aliquots of the resin-bound compound rather than cleaving all the compound bound to one resin bead at once. When using a multiple release system the compound in solution can be submitted to different bioassays, followed by structural determination of the biologically active substance in compound mixtures (see Section 4.2.1.4). This can be accomplished, e.g., by the use of a three-armed linker that selectively releases compounds at different pH optima [52], [53] or of a photochemically cleavable linker which releases compounds into solution by controlled irradiation [54], [55].

3.2.1.2. Reaction Portfolio

The synthetic repertoire of solid-phase organic chemistry has been growing rapidly in the last years and has expanded its scope in the complexity of compounds synthesized on solid-phase. However, so far only a small percentage of chemistry in solution has been transferred into reliable solid supported protocols [44–47]. This fraction includes multicomponent reactions [56–58]. Two ISIS-based databases have been established covering the solid-phase synthesis literature: solid-phase organic reaction (SPORE) database (from MDL Information Systems and FIZ Chemie Berlin) and Synopsys database (from Synopsys Scientific Systems together with Oxford Diversity).

In combinatorial synthesis the reactions must operate with reliable yield on a structurally broad set of building blocks to provide a multitude of almost pure final compounds under identical conditions. In the most time- and labor-intensive step, selected building blocks are "rehearsed" individually through reactions in the solid phase format, under conditions mimicking those that will be faithfully used in the final combinatorial synthesis. Since it will often be impractical to examine every member of the desired library to confirm its presence, building block combinations that are anticipated to represent worst case scenarios (e.g., with respect to steric and/or electronic factors) are studied and optimized, with problematic building blocks being excluded from the library construction.

In contrast, using an optimized synthesis sequence the combinatorial libraries can be constructed comparatively rapidly and efficiently as long as the building blocks are commercially available or readily accessible.

3.2.2. Synthesis in Solution and Liquid-Phase Synthesis

In the literature few examples exist for combinatorial syntheses in solution [59], most of them single-step parallel syntheses of individual compounds or "reagent-mixture" synthesis of compound mixtures. The use of supported reagents offers opportunities for improving the purity of compounds prepared [60–63]. A complementary approach uses a solid-supported scavenging agent [64–67], nucleophile or electrophile, to remove excess reagents.

An extension of the combinatorial synthesis in solution is achieved by the use of soluble polymeric supports [68], [69] which combines some of the advantages of chemistry in solution and on solid phase. The so-called *liquid-phase combinatorial synthesis* is based on the physical properties of poly(ethylene glycol) monomethyl ether. The polymer is soluble in a variety of aqueous and organic solvents which allows reactions to be conducted in homogeneous phase whereas the propensity to crystallize in appropriate solvents facilitates the isolation and purification of the compound at each step of the combinatorial synthesis.

One of the newer approaches which have yet to be seriously exploited involves the use of fluorinated hydrocarbons [70] to allow further options in the phase separation.

4. Characterization of Combinatorial Libraries

The combinatorial synthesis is followed by the analytical characterization and the biological evaluation of the compound library. Essential elements are the bioassays employed for high-throughput screening (→ High-Throughput Screening) and the methods available for structural elucidation of compounds that emerge from the biological evaluation of these compound libraries, termed as hits. The strategies used depend on the library format – separate single compounds or mixture of compounds, resin-bound compounds or compounds in solution.

4.1. Analytical Characterization

Since in a combinatorial synthesis the amount of compounds bound to a single resin bead is usually of the order of several hundred picomoles, the analytical methods for direct structural determination must be highly sensitive [71]. Efficient methods exist for the structural elucidation of peptides and oligonucleotides in the form of automatic microsequencing procedures (e.g., based on Edman degradation and DNA sequencing) [72]. For minute amounts of low molecular mass organic compounds, mass spectroscopic methods are the method of choice [73], [74], despite progress in the field of IR [75], [76] and NMR [77–80] spectroscopy. The sensitivity of modern mass spectrometry allows the structural determination of compounds in the high femtomolar range. Especially, electrospray mass spectrometry (ES/MS) (→ Mass Spectrometry, Chap. 4.9.) or matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF/MS) techniques (→ Mass Spectrometry, Chap. 4.8.5.) are used for resin-bound compounds.

Characterization of Compound Mixtures. If combinatorial libraries consists of compound mixtures (e.g., after cleavage from the resin beads), a reliable analytical characterization is difficult. In this case the utilization of mass spectrometry for analysis is based on the prediction of mass distribution of the library. Computer-generated distribution profiles can be compared with the actual profile obtained from the compound library [81], [82]. Evaluation of mass distribution detects synthetic problems based on incomplete coupling (shift toward lower molecular masses), incomplete deprotection, or unwanted library modification, such as oxidation, acylation, or alkylation (shift toward higher molecular masses). However, for a larger library of compound mixtures many different compounds will have the same molecular mass. This severely complicates structural determination and even makes it impossible at a certain mixture complexity.

For library analysis of compound mixtures reliable results are obtained by coupling mass spectrometry with HPLC or capillary electrophoresis (CE). In this arrangement, mixtures

of several hundred compounds can be analyzed. A comparison of MS, CE, and NMR for library characterization has been made in [81]. It was concluded that existing analytical techniques can provide sufficient information about prepared libraries.

In addition to the direct methods of structural analysis of libraries of compound mixtures, there are also indirect methods, which are particularly advantageous when working with larger compound libraries made by the split – pool synthesis (see Section 4.2.1).

Characterization of Single Substances. The analysis of separately synthesized single substances is much simpler than that of compound mixtures. Here, the yield and purity can be determined in the traditional way: purification by extraction, crystallization, or chromatography, gravimetrical determination of the yield and confirmation of the purity by elemental analysis, chromatography, or NMR.

4.2. Hit Identification in Combinatorial Libraries by High-Throughput Screening

Organic compounds are usually screened in solution in a 96-well microtiter plate format. Therefore, many bioassays are available, e.g., competitive receptor binding assays with radiolabeled ligands, functional assays, or cell-based assays. All these "solution-phase" bioassays, in principle, can be adapted to high-throughput screening of combinatorial libraries. Besides the growing number of compounds to be tested, the costs for a single bioassay (ca. $ 5 per well) is the main reason for the current trend to miniaturize the assay format towards 384- or 1536-well microtiter plates. (Since the wells of 384- and 1536-well plates are smaller, less substance, solvent, enzyme, etc., is required for one plate, thus reducing the cost per well). In an ultrahigh-throughput screening it should be possible to test more than 100 000 compounds per day.

In the case of combinatorial libraries comprising mixtures of solid-bound compounds the compounds can be screened still covalently attached to the solid support ("on-bead" screening, see Section 4.2.1.1) and, after cleavage of the bond to the support, in solution as compound mixture or as single compounds, when the beads are spatially separated (see Sections 4.2.1.1, 4.2.1.2, 4.2.1.3, 4.2.1.4).

The trend in bioassays is clearly towards examining the test compounds in solution. The results are not influenced by undesired interaction with the solid support. Experiences with "on-bead" assays were sometimes disappointing because even compounds that were known to be biologically active in solution did not bind to a detectable extent to the biological receptor when attached to the bead. Moreover, assaying compounds in solution is probably more pharmacologically relevant. In addition, screening on solid support is not applicable to intracellular targets when a whole cell assay is used.

In the following sections screening strategies for the identification of biologically active compounds (*hits*) in combinatorial libraries are summarized, especially for the most complicated situation when combinatorial libraries of compound mixtures are tested. Here, the exact identity of the compounds has been lost during the synthesis.

4.2.1. Strategies for Libraries of Compound Mixtures

4.2.1.1. On-Bead Screening

Combinatorial libraries can be screened, while the compounds are still attached to the resin beads or onto a surface [17], [18], [83–85]. Thus, the solid support (often TentaGel resin) and its linkers must be soluble in water and for quantitative results (e.g., structure – activity relationships) the beads must be uniform in both size and loading capacity.

The solid-bound library is treated with a labeled soluble biological target. For many studies a fluorescent label has been employed because of the high sensitivity of fluorescent detection. The labeled receptor binds to those resin beads that are derivatized with compounds that have the highest affinity to the biological receptor. The labeled beads are then selected followed by structural elucidation of the support-bound compound (see Section 4.1). The identity of the bioactive substance can be limited to a few alternative structures by mass spectrometric determination of the molecular mass. Very efficient,

automated methods have been developed to isolate the labeled beads, for example, by use of a fluorescence-activated cell sorting instrument [84].

This on-bead screening is particularly useful for libraries of several thousand to million compounds and isolation of a few active compounds from many inactive ones. By using an on-bead assay, the screening of a library of 10^7 resin-bound compounds can routinely be accomplished by one person in one day. One advantage of this method is that, once the library has been prepared and assayed, the remaining compounds may be reused for different biological assays. However, all of the difficulties of screening on the solid support remain.

4.2.1.2. Deconvolution

Three deconvolution strategies can be used for the structural determination of the biologically most active compounds in a combinatorial library comprising mixtures of up to several thousand compounds: (1) iterative deconvolution [27], [86], (2) deconvolution by positional scanning [87–89], or (3) deconvolution by orthogonal libraries [90–92].

4.2.1.2.1. Iterative Deconvolution

The iterative deconvolution method [27], [86] involves preparation of a series of spatially separated sublibraries comprising compound mixtures (termed pools) in which the identity of the building block at least at one position is known and at the remaining positions all combinations of building blocks are incorporated. This can be achieved, e.g., by omitting the final pooling step of the split – pool synthesis. Each pool is screened and the compound mixture with the highest biological activity indicates the importance of the building block at that defined position. On the basis of this result the split – pool synthesis is repeated with the selected building block at the initial defined position in order to prepare pools where the next defined position is introduced. Each pool is evaluated for biological activity in order to select the optimal building block at the additional defined position. The remaining positions are then identified sequentially through an iterative procedure of (re)synthesis and screening, as illustrated schematically in Figure 10 with a generic scaffold.

The iterative deconvolution procedure has been applied successfully to determine the biological active structure directly, but several issues should be considered. Firstly, as the number of compounds in a pool increases, lower concentrations of each compound must often be used in order to maintain the solubility of all the compounds in the pool. Compounds that have modest activity therefore may be not detected. Secondly, the biological activity observed for a given compound mixture depends on both the activity and abundance of the active compounds in each pool, i.e., biological activity is generally a result of the sum of more then one biological active compound. Thus, the compound mixture that shows the greatest biological activity does not necessarily contain the most potent compound(s) [93–96]. Thirdly, the iterative resynthesis and biological evaluation can be a time-consuming and laborious process.

A number of modification have been reported in order to address these complications. JANDA has noted that during the first split – pool procedure, resin can be saved at each cycle immediately prior to resin pooling. This resin can later be used as an intermediate in the iterative resynthesis and deconvolution procedure (recursive deconvolution) [97]. This results in considerable savings in time and effort.

4.2.1.2.2. Deconvolution by Positional Scanning

In the positional scanning approach for deconvolution [87–89], originated by HOUGHTEN and coworkers for peptide libraries, separate sublibraries are prepared, each of which contains a single defined building block at one position and a mixture of building block at the others. The number of sublibraries is equal to the number of variable positions in the substitution pattern. This method resorted to a hybrid of split – pool and parallel synthesis. Each positional sublibrary is then screened to directly determine the building block at each defined position that contributes most to biological activity (see Fig. 11).

Figure 10. Iterative deconvolution procedure illustrated by generic combinatorial library of a scaffold containing four variable building blocks A, B, C, and D and in total 256 compounds

Figure 11. Deconvolution by positional scanning illustrated by a generic combinatorial library of a scaffold containing four variable building blocks A, B, C, and D and in total 256 compounds
Procedure as described in the text.

By combining the positive screening results from all series of sublibraries the whole structure of a highly biological active compound can be deduced directly. In theory, if only one compound was active in the library, activity corresponding to that compound would be found in the one mixture of each sublibrary containing that compound. In reality, the same result is seen, but the activity generally results from the sum of more than one active compound. Anomalous results are seen if the activity is due to the sum of many weakly active compounds.

However, if in one position there is no clear preference for a definitive substituent, all combinations of this substituent must be synthesized in order to find the most active compound. Although active compounds are identified without iterative synthesis using positional scanning, in comparison with iterative deconvolution there is an increased likelihood that the most potent compound(s) will not be identified [98], [99].

The advantage of positional scanning over iterative deconvolution is that the sublibrary syntheses are carried out at once. But the number of split and pool operations that would be required for library synthesis is rather high so that building block mixtures are used in several of the library synthesis steps in order to reduce the number of operations. A thorough examination of the theoretical and experimental aspects of

iterative and positional scanning deconvolution has been published [98].

4.2.1.2.3. Deconvolution by Orthogonal Libraries

A method similar to the deconvolution by positional scanning was developed independently by Pirrung [90], [91] and Déprez [92]. This method has been termed orthogonal library approach or indexed library approach by other authors [100]. With respect to deducing structural information from the screening results this approach involves preparing two series of orthogonal sublibraries consisting of compound mixtures.

The combinatorial synthesis of orthogonal libraries involves the synthesis of two series of sublibraries. In the first series, each of the building blocks A_n reacts separately with a stoichiometric quantity of an equimolar mixture of the building blocks $B_1 - B_x$ and in the second series, each building block B_m reacts separately with an equimolar mixture of the building blocks $A_1 - A_x$. This synthetic approach provides compound mixtures, in which the identity of either the building block A or the building block B is fixed. This synthetic procedure results in each compound being formed exactly twice, and every pair of mixture has exactly one compound in common.

Here, a positive result for any given sublibrary in a biological assay identifies the fixed part of an active compound. By combining the positive results from both series of sublibraries the whole structure of an active component can be deduced directly. Moreover, this form of internal control allows the recognition of false positives in the biological evaluation process. Assignment of activity to a certain structure is possible by simple comparison, that is, without time consuming deconvolution or new synthesis. However, as in the case of the positional scanning method, it seems to be necessary to employ building block mixtures in each of the synthesis steps in order to reduce the number of split – pool operations.

4.2.1.3. Encoding

An alternative strategy with respect to structural determination of active compounds emerging from the biological evaluation of compound mixtures is to label the compound during the split – pool synthesis (encoding or tagging) [9], [101–105]. Here, instead of the structure of the biological active compound the corresponding more accessible (chemical) code is determined.

Chemical Encoding Strategies. In the chemical encoding strategy in general, resin linkers containing two orthogonally protected functional groups are used to allow the concurrent synthesis of both the compound of interest and encoding compounds (so-called tags), on the bead, which upon cleavage are sequenced or otherwise decoded to determine the structure of the compound of interest.

The tags may be added to provide an encoding sequence whereby the structure of the tag encodes for the building block and the location in the sequence encodes for the library synthesis step (oligonucleotides [9], [101–105] and peptides [106–110] as sequenceable tags, Fig. 12 A). The advantage of oligonucleotides and peptides as tags lies in the sensitivity and possibility of sequencing tens or hundreds of samples of nucleic acid codes in parallel (see Section 4.1), However, its application for coding organic libraries is rather limited due to the tendency of DNA and peptide tags to break down under the often very rough conditions of organic synthesis.

Alternatively, each tag may be added individually to the resin [111–117]. In this case the tags must encode for both the building block structure and the step in the library synthesis (haloaromatics as nonsequenceable tags, Fig. 12 B [111–115]).

For each tagging approach, a orthogonal chemistry between the tags and compounds of interest has to be determined, i.e., the compound itself must not be altered during addition of the tag. Those compounds are chosen as encoding compounds that can be easily identified by well-established highly sensitive analytical microtechniques even at very low concentrations.

In all cases, such a coding strategy is, of course, valid only if the relationship between support, compound and the code molecules remains intact. This provides no problem if biological testing is carried out with the support-bound compound. After testing and cleavage the active compound is identified by reading the

Figure 12. Encoded combinatorial libraries by (A) sequenceable chemical tags (oligonucleotides and peptides) or (B) by nonsequenceable chemical tags (haloaromatic phenol ethers)

code. However, the assay is usually carried out with dissolved compounds. Then, the synthesized compound can be selectively released from the support for the biological assay in solution (see Section 4.2.1.4), while the encoding strand is retained on the bead for later structural elucidation. This procedure requires that the solution containing the compound be spatially addressable to the solid support from which it originated to allow decoding.

Nonchemical encoding strategies, see Section 3.1.1.2.

4.2.1.4. Multiple Cleavable Linkers

Lebl [108], [118–121] and Baldwin [114], [115] first reported a strategy, in which the advantages of performing assays in solution and structural determination of resin-bound compounds are combined. This method is based on multiple cleavable linkers (see Section 3.2.1.2).

The compound library is divided into mixtures of up to several hundred compounds (see Fig. 13). In the first step about one-third of each respective compound bound on a macrobead (about 600 – 800 pmol compound per bead) is split off into solution for biological evaluation. Experiments performed indicate that an optimal mixture complexity is about 20 compounds per mixture [122]. In a second step the collection of beads corresponding to the greatest biological activity is then redistributed in smaller mixtures. Then a further aliquot of the respective compound is released and assaying. Ideally, the beads are rearrayed separately for direct identification of the compound responsible for biological activity ("single bead assay"). The structure of the bioactive compound can then be determined from the remaining resin-bound compound (often only femtomoles) by the analytical method described in Section 4.1.

4.2.2. Strategies for Libraries of Separate Single Compounds

If combinatorial libraries of separate single compounds are prepared by parallel synthesis, elucidating the structure of biological active compounds does not pose a problem, because the site of synthesize is clearly associated with the structure being synthesized (see Section 3.1.2), given that the desired product was build up during synthesis.

One of the major advantages of parallel synthesis is the possibility to compare the bioactiv-

Figure 13. Screening scheme of combinatorial libraries by the use of multiple cleavable linkers: Two-stage screening and then identification of the biologically active compound.

ity of the compounds within the library directly. Thus, the establishment of structure – activity relationships is possible, which is especially important during the drug optimization process. However, the screening capacity may still be a limiting factor, especially during lead optimization (where quite often assays are not automated) or if multiple measurements for dose – response curves are required.

4.2.3. Conclusion

Whether the synthesis and biological evaluation of combinatorial libraries comprising separate compounds or compound mixtures will predominate is difficult to say at present. There are as many examples of both strategies in the literature. It is unlikely that a general strategy will emerge in the future, since the choice of format will always depend on the particular problem in hand.

If compound mixtures are used, significantly more substances can be synthesized and tested per time unit. However, a potential disadvantage is that the initial assays are performed on mixtures of compounds, which may result in some potent library members being overlooked. Although the overall activity of a particular mixture could be poor, it might contain the most active compound in the library. Furthermore, problems with false positives and negatives are known to occur in testing mixtures. This is an important

issue – for which as yet only few guidelines exist – which apparently depends on the particular assay being examined. A common view is that one can afford to miss some active compounds during screening because of the large number of test substances – a sufficient number of interesting compounds for lead discovery will still be detected. Time saved by working with mixtures can, however, be partially or completely lost by the effort required for structural elucidation, that is, new synthesis of less complex sublibraries or single compounds.

5. Automation and Data Processing

5.1. Synthesis Automation and Data Processing

When the size of a combinatorial library reaches thousands of separate single compounds or compound mixtures, manual synthesis and testing against a biological target will hardly be manageable in a acceptable time frame. Therefore, the advent of combinatorial chemistry for the high-throughput synthesis of compounds has driven the advancement of automated methods for synthesis [123], [124] as well as requisite pre- and post-synthesis operations, i.e., resin loading, reagent and resin delivery, compound isolation, purification, and analysis.

Ideally, a fully automated process exists from the combinatorial parallel synthesis to compound isolation, delivering the compounds in a standard 96-well microtiter plate for the following biological high-throughput screening.

Most of the proprietary marketed automated synthesizer derive from instrumentation suitable for multiple peptide synthesis and from pipetting robots. These synthesizers preclude reaction conditions necessary for some organic transformations – especially carbon – carbon coupling reactions using air- or moisture-sensitive reagents that require inert atmosphere – and therefore introduce constraints upon library synthesis. That is why reactor blocks have been elaborated incorporating features most important to synthetic organic chemistry – both solid-liquid-phase synthesis or synthesis in solution. These features include temperatures between – 78 °C and 150 °C and inert atmosphere as well as using a wide variety of organic solvents. Furthermore, reactors for solid-phase synthesis require some mechanism for filtration and washing of the resin-beads (for representative reactors see Section 3.1.2.1).

The architecture of an automated synthesis system can be modular or integrated, open or closed. In a *modular computer-controlled robot system*, all liquid transfers (addition of solvents or reagents and washing solutions) take place in a central module constructed around a robot. The charged reaction vessels are then transferred to special incubation modules, where they remain for the duration of the reaction, while the central module is again available for further operations. In the *closed (nonrobotic) concept,* reagent and solvent are permanently interconnected with the reaction vessels by means of tubes and valves to insure an inert, anhydrous environment. Automation in high-throughput synthesis is still being developed by instrument and robotics companies as well as pharmaceutical companies. Examples are ACT496(MOS) (AdvancedChemTech), Genesis (Tecan), Nautilus(TM)2400 (Argonaut Technologies, Inc.) [125], RAM(TM)Synthesizer (Bohdan Automation, Inc.), Sophas(TM3) (Zinsser Analytic), Syro(TM) (MultiSynTec), and Zymark robotic workstation (Zymark, Inc.).

Automated combinatorial chemistry will demand a computer control of processing instrumentation. A *serial processing system* performs all operations on one sample before proceeding to the next one. On the other hand, automated synthesizers that processes samples *in parallel* perform the same operation on a plurality of samples before proceeding to the next operation. Parallel processing significantly improves the throughput and efficiency of automated synthesis systems. Furthermore, efficient software tools are necessary to program the synthesis run, to retain records of the synthetic operations or the biological testing and to handle the huge amount of compounds and corresponding data with respect to compound searches or data interpretation [126].

Current automated instrumentation for high-throughput synthesis are still below the capacity of the well-established high-throughput screening of compounds. Some instruments can produce 1000 to 2000 compounds per day by parallel synthesis. The time it will take to achieve

an automated synthesis capability that is equal to screening throughput is not yet known. By performing biological binding experiments in microtiter plates and employing both special pooling strategies and automation, nowadays 10 000 – 50 000 compounds can be screened against a given biological receptor in a single day with a good level of reliability (see also Section 4.2).

5.2. Automated Purification

In principle combinatorial synthesis does not create analytically pure compounds even though the applied chemistry might be optimized. With respect to structure – activity relationships the compounds evaluated in lead optimization should be as pure as possible. In high-throughput screening for lead finding the compounds are usually tested without purification. If the purity becomes a severe problem, it must be considered to purify all compounds before screening or to purify only the active molecules.

If *HPLC purification* is necessary, a one-column system can purify about 100 samples in milligram scale in one day. In this case it is advantageous to use an LC – MS system where the fraction collector is driven by the mass spectroscopic information because all fractions are already analyzed and ideally a reformatting step in the 96-well format is not required. HPLC-systems using more than one column in parallel are rare on the market. A commercially available system from Biotage consists of four columns driven by one pump and an individual fraction collector for each column. However, the system is not connected on-line to a MS and all fractions have to be analyzed off-line by MS. This may cause difficulties in sample-tracking and reformatting into the 96-well format, which should be controlled by an appropriate software.

Solid-phase extraction might be an alternative to HPLC separations, especially when large libraries are synthesized for high-throughput screening. Many of the modules for solid phase extraction can handle 96 samples in an microtiter plate array in parallel either manually or automatically, depending on the system. Solid-phase extraction is suitable to eliminate very polar or unpolar byproducts or salts, Examples of equipment include Roliman-96 (EPR Labautomation), Microlute (Zinsser Analytic), Genesis SPE (Tecan), ASPEC XL4 (Gilson, and Abimed Analysen-Technik), VacMaster (ict), and Baker spe∗12G System (J. T. Baker).

6. Library Design and Diversity Assessment

Combinatorial libraries serve two distinct functions in the drug discovery process, lead identification and lead optimization (see Fig. 1), which dictate their size and composition.

A compound library suitable for the discovery of a novel lead, where a priori no specific structure or substructure is obligatory as a starting point, will initially consist of a large number of compounds within a broad structural range (so-called "generic", "unbiased" or "random" library). Thus, the chance to identify a compound of significant affinity for the novel biological target or an alternative lead for a known biological target will be increased in random screening. On the other hand, in the case of lead optimization the compound library will be invariably of a more limited size with close structural resemblance to the original lead structure (so-called "focused", "biased" or "directed" library). Most drug development processes include a series of synthesis cycles within a targeted screening in order to meet a set of predetermined criteria for a drug candidate.

Thus, the library design (compound selection for combinatorial synthesis) as a central element in combinatorial chemistry depends markedly on the intended use of the library (see Table 2). In the case of generic libraries the best overall strategy for library design is rather blurred, and a variety of approaches are under investigation. One approach favors using structural motifs, which have distinguished themselves by appearing frequently in previous potent drugs or drug candidates, so-called "privileged" structures. One of the first examples of this type was provided by Ellman and coworkers [127–130] in the preparation of libraries of benzodiazepines, an important class of heterocycles that have found widespread use in the pharmaceutical industry. Another approach is to incorporate key recognition elements for receptor binding (pharmacophoric patterns: pharmacophores are

those structural features of a molecule required for the particular biological activity) that are relevant to the particular biological target under investigation [131]. These pharmcophoric patterns are used to provide a fingerprint of the specific binding characteristics. A third approach is to select stable compounds upon which only a few or no therapeutic agents or candidates have been based, but which are straightforward to prepare with multiple sites available for the display of different functionalities.

Table 2. Library design in the case of lead finding and lead optimization

	Lead finding	Lead optimization
Library type	generic	focused
Library size	huge ($\gg$ 10 000 compounds, $<$ 1 mg per compound)	modest ($\ll$ 10 000 compounds, $>$ 1 mg per compound)
Structural goal	no specific initial	specific (lead oriented)
Structural diversity	broadest	relatively narrow
Building blocks	any diverse	specific according to retrosynthesis
Synthetic strategy	flexible	well defined
Screening goal	many biological targets	one biological target or target class

6.1. Diversity Assessment for Selection of Building Blocks or Compound

The synthetic effort towards combinatorial libraries of several hundred thousands compounds is considerable. Therefore, computer-based techniques were introduced to reflect and analyze compound libraries to enhance the composition, while constraining their size.

Several groups have validated physicochemical or structural descriptors to quantify the similarity or so-called molecular diversity of compounds and compound libraries [132–136]. Representative approaches are based on physicochemical descriptors i.e., on log P, where P is the octanol-water partition coefficient, or on molar refractivity, 2D descriptors (2D fingerprints, atom pairs), or 3D descriptors in connection with the 3D model of the biological target (CoMFA, 3D fingerprints) (→ Information and Documentation). Examples of diversity profiling using 2D versus 3D descriptors are given in [137], [138]. One of the basic flaws in the concept of a diversity parameter is the lack of evidence that it correlates directly with biological activity of the compounds.

The computer-based library design process includes modules for the selection of the building block sets, the creation of the corresponding virtual compound library, and the selection of the compounds to be synthesized and screened. The selection procedure for the generation of a generic library with a broad range of structurally unrelated compounds by comparing the building blocks or the compounds of the virtual library consists of calculating descriptors for the compounds, weighting them according to an algorithm, and then calculating a similarity coefficient (e.g., Tanimoto coefficient). Part of the selection process is to determine the availability and cost of reagents used as building blocks. The members of a building block set should reflect a broad range of physicochemical properties, functionalities, charges, and conformations. Databases of chemicals are available for this purpose, e.g., the Available Chemicals Directory by MDL Information Systems, a collection of chemical products offered by more than 200 chemical suppliers and totaling well over 400 000 compounds.

Modules in software programs for diversity analysis are, e.g., elector (Tripos), Jarpat (Daylight Chemical Information Systems), C^2-Diversity (Molecular Simulation), and Chem-X (Chemical Design). In the context of management of compound libraries software programs such as Project Library, Legion, or UNITY (all by Tripos) are available.

6.2. Iterative Optimization Methods

The interpretation of the biological data resulting from library screening drives the new (secondary, tertiary, etc.) library design, creating an iterative cycle of combinatorial library synthesis and biological evaluation. One challenge in lead optimization is to capture the data and to build structure – activity relationship (SAR) and quantitative structure – activity relationship (QSAR) models, based on a larger data set. The power of combinatorial chemistry and in this particular case the efficacy of (automated) parallel synthesis is to produce hundreds of analogs in a short time frame. This will contribute to the faster development of a drug candidate with the

desired biological activity. Furthermore, other main tools of traditional drug development including structure- and mechanism-based drug design will be integrated in the library design.

An alternative computer-based approach minimizing the number of compounds to be synthesized is the iterative use of genetic algorithms [139], [140] in library design. Here, in order to find biologically active compounds from a virtual library of hundred thousand compounds only a small number of randomly selected compounds are synthesized, followed by biological evaluation. The most active compounds are selected, which formed the parent generation of computation and synthesis of further compounds. In an example given in [142], this process is carried out with 20 compounds for each of the 20th generations so that in total 400 (0.25 % of the possible 160 000) reaction products were synthesized and tested. The compounds of the 20th generation were 2000 times more active against the biological target (thrombin inhibitor) than those of the first generation.

7. Economic Aspects and Industrial Case Studies

Since the beginning of the 1990s combinatorial chemistry has become a key technology in most pharmaceutical companies. Combinatorial chemistry is changing the drug discovery process (see Fig. 1). The importance of this technology is also indicated by several alliances between major pharmaceutical companies and small "Combi Chem" companies and library suppliers. From 1995 to 1997 alone, more than 60 of these agreements were signed, which typically included up-front payment, milestones, and substantial royalties on the sale of commercialized products [141], [142].

Combinatorial chemistry can contribute to drug discovery on the one hand by improving the finding of biologically active compounds (leads) in combination with high-throughput screening and on the other hand by acceleration of lead optimization resulting in an active drug candidate with a desired pharmacological profile.

Historically, the pharmaceutical compound collections range from several ten thousand to several hundred thousand compounds per company, depending on the size and history of the company. These compounds have long been regarded as the "crown jewels" of their respective R & D organizations. Assuming one newly synthesized compound per researcher per week and using $ 250 000 as the fully burdened cost per researcher per year, a 100 000 compound library approximates a $ 500 million investment in compound synthesis, patenting, and potential screening against biological targets [141]. In this context, combinatorial chemistry raises the opportunity to build up or amplify the number of compounds for high-throughput screening in a shorter period of time. Combinatorial chemistry companies such as Pharmacopeia report the generation of 100 000 compounds per calendar quarter and the use of robotic systems capable of analyzing 100 000 compounds per week.

Another aspect in many companies is the diversity of the compound pool. Typically, it contains many molecules with high structural similarity because they were prepared during lead optimization in which only slight variations on the architecture of the molecules were performed. The design and synthesis of diverse combinatorial libraries according to computational methods described in Chapter 6 may contribute to improve the overall diversity of a compound collection with respect to lead finding.

Thus, combinatorial chemistry is emerging as a time- and cost-efficient tool for drug discovery [143] although there are presently very few compounds in the clinic trails that were discovered utilizing combinatorial chemistry.

Scores of patents already exist in the field of combinatorial chemistry directed to methods of making libraries, devices used in these methodologies, assay methodologies, and on libraries themselves [144].

Combinatorial chemistry will probably not substitute traditional medicinal chemistry, it should be considered as one important tool in the process of drug discovery. Numerous possibilities for structural variations of a given compound, e.g., replacement of atoms in a ring system, change of ring size, rigidization through introduction of bridging units as well as large scale synthesis are still a domain of traditional synthetic chemistry.

8. Further Developments

The vast majority of combinatorial libraries of organic compounds have been designed to accelerate the drug discovery process. Beyond this, the application of combinatorial chemistry to problems of catalysis and material science promises to discover materials of industrial interest with novel catalytic, electronic, magnetic, optical, and mechanical properties. Moreover, the results from such experiments should significantly increase the theoretical understanding of relationship between structures and their properties, enhancing predictive ability even further.

Examples reflecting the current state of development in the field of inorganic solid-state substances with respect to material science and transition metal compounds with respect to (homogeneous) catalysis will be given in the next two sections.

8.1. Combinatorial Chemistry and Catalysis

The challenge in catalysis is to find catalysts with high catalytic activity and selectivity for given chemical transformations and to optimize them. In addition, the catalyst must fulfill technical demands such as satisfactory lifetime and regenerability. Despite extensive studies on structure – activity relationships and underlying mechanisms, many improvements in catalyst design arise from extensive empirical catalyst syntheses and mass screening. In chemical industry the acceleration of the catalyst development can have a large economic and ecological effect, because more than 90 % of current industrial processes involve catalytic steps.

Combinatorial chemistry is not yet widely used to accelerate the development of new catalysts [145–149]. Since 1995 some attempts have been made to apply combinatorial strategies to problems in stereoselective homogeneous catalysis, mainly by U.S. groups. Here, parallel synthesis of ligands, which can complex transition metals, were carried out on the solid phase according to combinatorial principles or at least according to combinatorial related strategies [150], [151]. This resulted in libraries of potential catalytically active transition metal compounds, which were tested to discover homogeneous catalysts for stereoselective synthesis. It is important to mention that the catalytic activity and selectivity could be markedly different, when the catalyst is still attached to the resin bead and after release.

To identify catalysts with desired properties from a compound library it is important to establish techniques for an high-throughput catalyst screening. In this respect the following important question has to be answered: Is it necessary to determine both the catalytic activity and selectivity simultaneously or is the measurement of only one of this characteristics sufficient for the catalytic reaction? In this context it has also to be taken into account that the catalytic activity and selectivity is inherently dependent on physical parameters such as temperature and pressure. A common view in catalysis is that it is possible to obtain selective catalysts in an iterative optimization cycle but that it is more difficult to reach turnover numbers which are sufficient from a technical point of view. Efforts in the field of rapid and parallel catalyst screening so far have focused on for example, the detection of heat liberation in the catalyzed reactions by noninvasive IR thermography [152] or of the catalytic reaction progress by spectrophotometric techniques [153], [154], when chromogenic reagents were used. The analytical results can be quantified and correlated with the catalytic activity.

The concept of developing catalysts combinatorially has great promises, but the proof of the concept has so far been elusive.

8.2. Combinatorial Chemistry and Material Science

Even though the chemistry of extended inorganic solids has been extensively explored, only limited general principles have emerged that allow to predict composition, structure, and reaction pathways for the synthesis of solid state compounds of industrial interest, such as superconducting or magnetoresistive materials. In light of these challenges, it seemed to be that combinatorial chemistry could be a way to the discovery of new solid state materials. However, up to now there are mainly Schultz, Xiang, and coworkers as well as the company Symyx, who have published results in this area of combinatorial chemistry since 1994 [155–162].

Unlike the discovery of new drug candidates, where the assayed properties are based on a molecule – molecule interaction, the property of interest in material science are based on the bulk properties of compounds. Thus, in this case parallel synthesis and characterization of each separate candidate is required.

SCHULTZ, XIANG, and coworkers [155–158] used thin-film deposition methods and physical masking-techniques to synthesize spatially defined libraries of solid-state thin films. The individual element precursors of interest were sequentially sputtered onto the surface of a single-crystal wafer of magnesium oxide or lanthanum aluminate through a series of physical masks. A different masking pattern was used for each element precursor, and the patterns were chosen so that every possible combination of the elements was found somewhere on the wafer (see Section 3.1.2.3). Subsequently, the coated wafer was subjected to thermal and oxidative treatment to form the final library of solid-state thin film.

Rapid detection systems for the physical properties of the thin films are also being developed including contact and rapid scanning probes. The properties of the resulting materials were then evaluated to identify promising candidates for further development.

In addition, improved methods for combinatorial processing are also being developed, in which not only composition and stoichiometry but also film thickness, processing temperature, pressure, and atmosphere can be varied. Multihead ink-jet deposition systems are being tested for generating libraries derived from solution phase precursors. These methods together with theoretical and empirical input may considerably facilitate both the material discovery process and the ability to test theoretical predictions and map phase diagrams.

1. Introduction

The basic problem in coronary heart disease or coronary insufficiency is an imbalance between oxygen supply and tissue requirement. The clinical signs of coronary insufficiency include chest pain, impairment of left ventricular function, and other signs of a compromised central circulation. *Angina pectoris,* the common symptom of coronary insufficiency, is usually associated with stress, emotion, or excess oxygen requirement due to exercise. This form is known as *secondary* or *effort angina.*

There has been interest in a form of angina caused by an absolute reduction in coronary blood flow associated with a spasm of a large coronary artery classified as *primary angina* [1]. This type of angina occurs at rest or during sleep.

Both types of angina are caused by myocardial ischemia or hypoxia, or both. Therapy must be selected on the basis of the type of angina because such drugs as β-adrenergic blocking agents are ineffective in and may actually exacerbate vasospastic angina (primary angina).

Most cases of angina are associated with atherosclerotic narrowing of one or more major coronary arteries, resulting in some degree of stenosis. When the stenosis reaches a critical point, there is exhaustion of compensatory autoregulatory mechanisms involved in maintaining coronary blood flow appropriate to requirement. When the reserve capacity for coronary dilatation is lost, increased demands for oxygen cannot be achieved and coronary insufficiency results as in secondary angina. Coronary anginal episodes can also occur in the presence of nearly normal arteries with minimal stenosis as a result of vasospasm of the artery and, consequently, reduction of flow.

2. Anatomy and Physiology of Coronary Circulation

2.1. Anatomy

The anterior surface of the heart is supplied by the left coronary artery, which originates from the aorta close to the valves. The coronary artery divides into a left anterior descending artery and a circumflex artery to supply the anterior surface of the left ventricle (Fig. 1). Atherosclerosis most frequently develops in these large surface (epicardial) arteries and can ultimately produce significant stenosis. Intramural penetrating branches leave the superficial arteries to penetrate the walls of the left ventricle. These give off branches to supply the superficial portions of the myocardium, the epicardium (a), and the deeper portions, the endocardium (b). Normally the large superficial arteries and penetrating arteries serve as conduits and account for only a small fraction of the resistance to blood flow.

The arterioles, however, account for a high fraction of the resistance to blood flow, and they are involved in autoregulation. However, the large conduit vessels demonstrate vasomotion, and in the presence of stenosis, vasospasm can produce a significant resistance to blood flow. Under the stimulus of chronic coronary insufficiency, collateral vessels develop to supply blood flow to a region in which the normal arterial circulation is blocked by complete stenosis.

2.2. Physiology

The coronary circulation is peculiar because it supplies the organ that generates the pressure for perfusion. During contraction (systole) the myocardial walls throttle circulation through the left ventricle. Because of the periodic compression of the coronary vessels, instantaneous coronary flow varies during each cardiac cycle. In the deeper regions of the heart, the endocardium, flow declines to zero at the height of systolic compression. Accordingly, most of the coronary blood flow occurs during dilatation (diastole) when the heart is in the relaxation phase.

The heart is dependent on flow and extracts 75 % of the oxygen from the arterial blood. An increased requirement for oxygen is normally met by an increase in blood flow through autoregulation. Balance between requirements of the tissues for oxygen and substrate and the blood supply is controlled by the arteriolar resistance vessels. When the oxygen partial pressure is decreased, adenosine is released from the tissue, effecting an increase in blood supply through local arteriolar autoregulation. This mechanism may fail in the case of a stenosis of a large artery. Under those circumstances, resting flow is maintained in regions distal to the stenosis by decreased regional arteriolar resistance, and demand for increased blood flow cannot be met because the arteriolar dilator reserve capacity is exhausted.

The heart has one of the highest oxygen requirements relative to blood flow rate. Oxygen extraction is almost maximal, and increased demands can be met only by increased blood flow. The partial pressure of oxygen in tissue and the concentration of anaerobic enzymes are lower in the subendocardium.

2.3. Pathophysiology

Coronary insufficiency is caused by an imbalance between supply and demand. Disturbances of the fine balance between supply and demand can occur (1) on the supply side by a spasm of a large coronary artery or (2) on the demand side by increased oxygen requirement that cannot be met by increased blood flow. Both conditions are associated with atherosclerotic changes, but this is not a necessary requisite in the case of a vasospastic episode.

The determinants of blood flow and oxygen supply include (1) perfusion pressure, (2) diastolic duration, (3) extravascular compression (systolic wall tension), (4) arteriolar resistance, and (5) large intramural artery tone [3]. The last is an important determination for the distribution of blood flow between the epicardium and endocardium and can be critical when autoregulation becomes exhausted. The extreme vulnerability of the subendocardium to ischemia is a result of mal-distribution. Normally, the resistance of large vessels accounts for 5 % of the total, but during maximal arteriolar dilatation, it can account for 20 % of the total resistance [2].

The requirement for blood flow and oxygen is determined by (1) heart rate, (2) contractile state, and (3) wall tension. The balance of supply and demand must be maintained for adequate oxygenation of the heart tissue.

There are two basic types of angina [1]: *primary angina,* which is caused by a reduction in blood supply due to vasospasm, and *secondary angina,* which results from an increased oxygen demand that cannot be met by an increase in blood flow. This is associated with a fixed obstruction of a major coronary artery. Although coronary blood flow is normal at rest, it cannot increase with the requirements of stress. Approximately 85 % of the patients have secondary angina, while only 15 % have primary angina. Some patients have a combination of both forms and stress may actually induce spasm. *Prinzmetal's angina* is an example of vasospastic angina with a differential electrocardiographic change compared with angina of effort [4]. Vasospastic (primary) angina occurs at rest, and secondary angina is associated with exercise, emotional changes, or stress.

2.4. Rationale for Treatment

The primary function of therapy is to restore the proper balance of supply and demand. The approaches to accomplish this depend on the pathogenesis [3]. In the case of *primary angina*, one must increase blood flow by eliminating the spasm. This can be accomplished by nitrates and calcium channel blockers [4]. In the case of acute vasospasm, relief can be achieved by sublingual, intracoronary, or intravenous administration of nitrogylcerin or calcium channel blockers.

Secondary angina is relieved by reducing the oxygen demand by one of the following means:

1) decrease in heart rate and prolongation of diastole (β-adrenergic blockers);
2) decrease in heart work by (a) decreasing in contractility (β-adrenergic blockers, calcium channel blockers), (b) reducing preload by venous pooling (nitrates), or (c) reducing afterload (calcium channel blockers);
3) redistribution of blood flow to favor ischemic endocardial regions (nitrates).

Three types of agents are effective in secondary angina: (1) vasodilators of large coronary arteries, nitrates being the example; (2) β-adrenergic blockers; and (3) calcium channel blockers [3]. Potent coronary arteriolar dilators such as dipyridamole and chromonar are not effective in secondary angina. The capacity to increase blood flow in normal regions of the heart is not associated with a therapeutic effect. In fact, potent coronary arteriolar dilators may actually produce a deleterious effect known as *coronary steal* by diverting the blood flow from ischemic regions to normal regions of the heart.

Improvement of Regional Oxygen Supply. Mechanisms to improve regional oxygen supply include:

1) increase of diastolic pressure gradient by reducing wall tension and/or increasing perfusion pressure (nitrates; β-blockers have the opposite effect);
2) increase of diastolic duration (β-adrenergic blockers);
3) decrease of extravascular compression and wall tension (nitrates and calcium channel blockers; β-blockers may increase);
4) large vessel dilatation and stenosis dilatation (nitrates);
5) redistribution of blood flow to the ischemic regions (nitrates, β-adrenergic blockers, and calcium channel blockers);

6) decrease of spasm (nitrates and calcium channel blockers).

Decrease of Oxygen Requirement. Mechanisms to decrease oxygen requirement are:

1) lowering of wall tension (nitrates; β-blockers increase);
2) decrease in heart rate (β-adrenergic blockers and calcium entry blockers);
3) decrease in contractility (β-adrenergic blockers and calcium channel blockers);
4) decrease of afterload (calcium channel blockers);
5) decrease of preload (nitrates).

3. Nitrates

3.1. Clinical Factors

Nitrates have been the first agents for prophylaxis and treatment of angina pectoris [3]. Over the past 100 years, they have proven to be useful in the treatment of all forms of angina. All nitrates have a similar pharmacological activity [5]. The major differences are of a pharmacokinetic nature, primarily concerning whether or not they are absorbed rapidly by the buccal mucosa and can be used sublingually to relieve an attack.

Nitroglycerin is effective sublingually within 30 s and has a duration of ca. 30 min. Other nitrates are not rapidly active sublingually and are of no value for treatment of an anginal attack. On the other hand, all of the nitrates currently used are effective orally, including nitroglycerin, isosorbide dinitrate, isosorbide-5-mononitrate, pentaerythrityl tetranitrate, and possibly mannitol hexanitrate and erythrityl tetranitrate; the latter two are less important.

In addition to the sublingual or oral route, nitrates are also administered intravenously or they are injected directly into the coronary artery in cases of vasospastic angina (primary angina) or congestive heart failure.

Transdermal preparations of nitroglycerin and isosorbide dinitrate are also available [6]. Percutaneous ointment of nitroglycerin was available many years ago but fell into disrepute. According to more recent studies, percutaneous administration provides protection for at least 4 – 6 h. Patients can be protected during the waking hours on a TID (three times a day) basis. Transdermal devices have been developed that permit absorption over a period of more than 24 h. However, protection over 24 h is questionable. This is not due to lack of constant blood level, but tolerance may develop. Peaks and troughs in blood levels are obviously necessary to provide protection over a prolonged period.

Headache is the major side effect of the nitrates. The existence of a tolerance to the nitrates is controversial. Certainly tolerance to the headache may develop, and there may be some degree of tolerance to the beneficial effect; however, this effect is not of sufficient magnitude to prevent its use.

3.2. Pharmacology of Nitrates

The most prominent pharmacological action of the nitrates is relaxation of vascular smooth muscle. The vasodilator action is possibly caused by bonding to sulfhydryl groups on the nitrate receptors in vascular smooth muscle; this increases the concentration of cyclic guanosin monophosphate, leading to vasodilatation [7].

The nitrate action on the peripheral vascular system appears to be more selective for the venous portion with increased distensibility. Venous dilatation results in a decrease in venous return and preload, enabling a decrease in the size and pressure of the left ventricle. In the coronary system, nitrates are weak transient dilators of small resistive vessels (arterioles), but they have a selective prolonged dilator action on the large coronary arteries [8], [9].

3.3. Mechanism of Relief of Angina

The venous dilator action decreases left ventricular size and oxygen consumption. Another factor that contributes to the beneficial effect is selective dilatation of large coronary arteries and collateral coronary vessels; this redistributes blood flow and increases perfusion of the ischemic endocardium [2]. In addition, the nitrates reverse coronary spasm associated with the large coronary arteries.

In summary, the nitrates relieve angina pectoris by decreasing myocardial oxygen demand,

by decreasing left ventricular wall tension with enhanced perfusion of the subendocardium and, in the case of vasospastic angina, by reversing the coronary spasm of large vessels [10].

3.4. Individual Nitrates Use

The nitrates that are used therapeutically include nitroglycerin, isosorbide dinitrate, isosorbide-5-mononitrate, pentaerythrityl tetranitrate, mannitol hexanitrate, and erythrityl tetranitrate.

Nitroglycerin [*55-63-0*], 1,2,3-propanetriol trinitrate, glyceryl trinitrate, $C_3H_5N_3O_9$, M_r 227.09, *mp* 2.8 °C (labile form) or 13.5 °C (stable form). For its preparation, see [11–16].

Trade Names. Nitro-bid (Marion), Nitrodisk (device; Searle), Nitrodur (device; Key), Nitrostat (Parke-Davis), Transderm-nitro (device, Ciba-Geigy), Deponit (Pharma-Schwarz), Nitrolingual (Pohl).

Isosorbide dinitrate [*87-33-2*] , 1,4 : 3,6-dianhydro-D-glucitol dinitrate, $C_6H_8N_2O_8$, M_r 236.14, *mp* 70 °C, is prepared from sorbitol [17].

Trade Names. Isoket (Pharma-Schwarz), Iso Mack (Mack), Isordil (Wyeth), Sorbitrate (Stuart).

Isosorbide-5-mononitrate [*16051-77-7*], 1,4 : 3,6-dianhydro-D-glucitol-5-nitrate, $C_6H_9NO_6$, M_r 191.14, *mp* 90 – 91 °C; for its preparation see [18–20].

Trade Names. Elantan (Pharma-Schwarz), ISMO (Boehringer-Mannheim), MonoMack (Mack).

Pentaerythrityl tetranitrate [*78-11-5*], 2,2-bis[(nitrooxy)methyl]-1,3-propanediol dinitrate, pentaerythritol tetranitrate, $C_5H_8N_4O_{12}$, M_r 316.15, *mp* 140 °C, is made by nitration of pentaerythritol [21], [22].

Trade Names. Peritrate (Parke-Davis), Dilcoran (Gödecke).

Mannitol hexanitrate [*15825-70-4*], mannitol nitrate, nitromannite, nitromannitol, $C_6H_8N_6O_{18}$, M_r 452.17, *mp* 106 – 108 °C, is made by nitration of mannitol [22], [23].

Trade Name. Not approved in the United States; Manexin (Beecham).

Erythrityl tetranitrate [*7297-25-8*], erythritol tetranitrate, erythrol tetranitrate, $C_4H_6N_4O_{12}$, M_r 302.12, *mp* 61 °C, is made by nitration of erythritol [22].

Trade Name. Cardilate (Wellcome).

4. β-Receptor Blockers

In step care therapy for the treatment of ischemic heart disease, the second stage is β-adrenergic blockage [3]. The drugs became available about two decades ago and are an important group in treatment of patients with ischemic heart disease (and hypertension) [24–27]. β-Blockage attenuates the β-adrenergic influences on the heart,

which include increased heart rate and increased contractility, both of which increase myocardial oxygen demand. With a compromised coronary circulation, coronary insufficiency results. β_1-Receptors are found in the heart, and β_2-receptors are found in bronchioles and vascular smooth muscle. During exercise and stress, adrenergic tone is increased, resulting in excessive stimulation of the heart, increase in heart rate, and possible decrease in coronary blood flow as a result of α-adrenergic stimulation.

4.1. Mechanism of Action

Like the nitrates, the β-blockers have multiple actions. They primarily act by blocking the β_1-receptors in the heart. This decreases the heart rate and contractility at rest and during excercise and also prolongs the diastolic perfusion time. The increase in the diastolic perfusion index permits redistribution with greater perfusion of the deeper endocardial regions of the ischemic area of the heart. The reduction in heart rate, contractility, and blood pressure then lowers the oxygen requirement. Therefore, β-adrenergic blockage reduces myocardial oxygen requirement and enhances blood flow to the ischemic region.

However, the mechanism of action comprises some negative aspects. Because of the decreased contractility, β-blockage can lead to some degree of heart failure. In addition, asthmatic patients can encounter bronchoconstriction because of the β_2-blocking action. There may also be an increase in coronary arteriolar tone when the β_2 influence is withdrawn. Likewise, peripheral vascular problems may arise because of vasoconstriction of the extremities.

4.2. Classification

Quantitative differences among the various β-blockers are due to such selective properties as cardioselectivity, intrinsic sympathomimetic activity (ISA), and membrane stabilizing activity. The last is of little consequence in treatment of angina because it refers to antiarrhythmic activity.

Cardioselectivity is determined by the balance between β_1- and β_2-receptor blockage. Cardioselective agents are selective for β_1-receptors and are less liable to produce side effects in patients with chronic lung disease, asthma, or peripheral vascular disease as compared to noncardioselective blockers.

Intrinsic sympathomimetic activity (ISA) or partial agonist activity relates to the β-agonist activity. Theoretically, compounds with ISA are less likely to cause extreme bradycardia or cardiac depression than compounds without ISA. Compounds with ISA are also supposed to be less prone to produce bronchoconstriction. However, the relative importance of this aspect has not been demonstrated in clinical use.

Noncardioselective agents without ISA include propranolol [*318-98-9*], with ISA are less likelytimolol [*91524-16-2*], sotalol [*959-24-0*], and nadolol [*42200-33-9*]; noncardioselective agents with ISA are oxprenolol [*6452-71-7*], alprenolol [*13707-88-5*], and pindolol [*13523-86-9*].

Cardioselective agents without ISA are metoprolol [*37350-58-6*], atenolol [*29122-68-7*], and those with ISA are acebutolol [*37517-30-9*] and practolol [*6673-35-4*]. The physical properties and preparation of these drugs are treated in a separate article (→ β-Receptor Blocking Agents).

Propranolol

Timolol

Sotalol

Nadolol

Oxprenolol

Alprenolol

Pindolol

Metoprolol

Atenolol

Acebutolol

Practolol

The drugs have different durations of action, and those that are considered long-acting include sotalol, nadolol, atenolol, and practolol. The choice of an agent for a particular patient is based primarily on the factors of duration of action and cardioselectivity.

5. Calcium Channel Blockers (Calcium Antagonists)

The calcium channel blockers have been investigated intensively in the past decade. The first was verapamil, which was followed by nifedipine and diltiazem [28]. Originally, verapamil was thought to be a coronary dilator and possibly to have β-blocking action, and nifedipine was classified primarily as a potent coronary dilator. According to the work of Fleckenstein [29], the mechanism of action of these compounds is *calcium antagonism.* Later the term *calcium entry blocker*, or *calcium channel blocker,* was adopted because these compounds inhibit the slow influx of calcium ions into the cardiac muscle and reduce the transcellular passage of calcium ions in vascular smooth muscle. In contrast to the β-adrenergic blockers, these compounds are chemically heterogeneous and have differing pharmacological, electrophysiological, and hemodynamic properties [30]. Their common feature is blockage of calcium entry into the cell.

In both cardiac muscle and vascular smooth muscle, calcium ions are responsible for the coupling of excitation to contraction. Blockage of this coupling causes relaxation of vascular smooth muscle and reduced myocardial contractility. However, uncoupling in the cardiac muscle can finally result in cardiac failure. Some of the agents are unique in the treatment of vasospastic angina (primary angina) and effort angina (secondary angina) because the vascular smooth muscle is very sensitive to their effects [28], [29].

5.1. Cardiovascular Effects

All of the calcium channel blockers exert negative inotropic effects on the isolated myocardium, but this does not appear to be a significant factor in therapeutic use. Lack of a negative inotropic effect in humans is attributed to the reflex sympathetic discharge associated with the vasodilator action of these agents. Furthermore, the dose that depresses the heart is usually ten times that producing coronary dilatation. Myocardial oxygen consumption is usually decreased primarily as a result of decreased afterload (peripheral vasodilatation) and the small negative inotropic effect.

Calcium channel blockers dilate the small and the large coronary arteries [30]. This distinguishes them from the potent coronary dilators, which act primarily on the small vessels, and the nitrates, which act primarily on the larger vessels. In addition, calcium channel blockers reverse the spasm of the large coronary arteries that occurs in vasospastic angina or is induced by ergonovine [4], [28]. Blood flow to the normal and ischemic regions can be increased, indicating that the calcium channel blockers can increase collateral blood flow. Finally, calcium channel blockers have potent peripheral dilator actions and reduce peripheral resistance.

Verapamil has some distinctive electrophysiologic effects; it reduces conduction through the atrioventricular node. As a result, verapamil is exquisitely useful in the treatment of paroxysmal

supraventricular tachycardias [28], [30]. Other calcium channel blockers, such as nifedipine and diltiazem, do not have this property and are not useful in treatment of this arrhythmia. Resting heart rate may be increased by nifedipine, decreased by diltiazem, and scarcely affected by verapamil.

5.2. Therapeutic Use

Calcium channel blockers are recommended for angina pectoris of all types, including primary and secondary angina. Because they prevent or reduce a spontaneously occurring spasm of large coronary arteries, the calcium channel blockers are recommended for the treatment of Prinzmetal's angina and other vasospastic phenomena. A vasospasm may also be involved in angina of effort, but there it primarily acts by reducing myocardial oxygen consumption attributed to reduced afterload and decreased contractility.

5.3. Individual Calcium Antagonists

Many agents show some degree of calcium entry blockage, but the most clinically useful drugs are selective for calcium entry (type A agents) [31–34]. Included in this group are verapamil [*152-11-4*], nifedipine [*21829-25-4*], diltiazem [*33286-22-5*], and other more recently developed compounds such as nimodipine [*66085-59-4*], nitrendipine [*39562-70-4*], nicardipine [*54527-84-3*], and nisoldipine [*63675-72-9*].

Type B calcium channel blockers also block sodium entry; they include prenylamine [*390-64-7*], fendiline [*13042-18-7*], and perhexiline [*6621-47-2*] [35–37]. Lidoflazine [*3416-26-0*] and bepridil [*74764-40-2*] [38–40] may be included as well. The latter two compounds were initially developed as conventional coronary dilators, but later were shown to have some calcium antagonist activity. The physical properties and the preparation of these drugs are treated in a separate article in this Encyclopedia (→ Calcium Antagonists).

6. Large Coronary Artery Dilators

Several new agents selectively affect the large coronary arteries like the nitrates [41]. The effects on the smaller coronary arteries are modest and probably of little significance in ischemic regions. Molsidomine, trapidil, and nicorandil are successful in treating secondary angina. They have different chemical structures but common pharmacological features that contribute to their antianginal efficacy. All relax the large coronary arteries and collateral blood vessels. Perfusion of the subendocardial region of the ischemic zones is enhanced because of redistribution in favor of the deeper myocardial regions. Like nitroglycerin, these compounds increase venous capacity and reduce myocardial preload and myocardial oxygen consumption [42–50]. Their effectiveness in vasospastic angina has not yet been clearly demonstrated.

Additional effects of nicorandil are (1) a reduction in myocardial infarct size following coronary occlusion, (2) a reduction in the acidosis and lactate content of the ischemic region, and (3) reversal of spasm of the large coronary artery produced by acetylcholine. Trapidil also inhibits platelet aggregation and has a hypolipidemic effect. Molsidomine has been demonstrated to have an antithrombotic effect. These ancillary actions may contribute to the overall antianginal effect, but the major contributions presumably come from the large coronary artery dilatation and redistribution, which favor subendocardial perfusion.

Molsidomine [*25717-80-0*], N-(ethoxy/carbonyl)-3-(4-morpholinyl)sydnone imine, *N*-carboxy-3-morpholinosydnonimine ethyl ester, $C_9H_{14}N_4O_4$, M_r 242.23, *mp* 140 – 141 °C; for its preparation, see [51], [52].

Trade Names. Corvaton (Cassella-Riedel), Molsidolat (Hoechst), Morial (Takeda), Motazomin (Takeda).

Trapidil [*15421-84-8*], *N,N*-diethyl-5-methyl-[1,2,4]triazolo[1,5-*a*]pyrimidin-7-amine, 7-diethylamino-5-methyl-*s*-triazolo[1,5-*a*]pyrimidine, $C_{10}H_{15}N_5$, M_r 205.27, *mp* 98 – 99.4 °C, 102 – 104 °C (from heptane); for its preparation, see [53], [54].

Trade Name. Rocornal (VEB Deutsches Hydrierwerk, Mochida).

Nicorandil [*65141-46-0*], *N*-[(2-nitrooxy)-ethyl]-3-pyridinecarboxamide, *N*-(2-hydroxyethyl)nicotinamide nitrate (ester), $C_8H_9N_3O_4$, M_r 211.17, *mp* 92 – 93 °C; for its preparation, see [55], [56].

Trade Name. Sigmart (Chugai).

7. Potent Coronary Arteriolar Vasodilators

The class of highly effective coronary arteriolar dilators includes dipyridamole, which was the first drug of this kind, and chromonar. Both compounds relax the coronary arterioles (resistance vessels) selectively, which leads to maximum blood flow of the normal regions. However, they do not increase blood flow in the ischemic regions. Because the normal regions are preferred, these drugs can actually cause "coronary steal" by diverting blood flow from the ischemic regions to the normal regions [57], [58]. These compounds are not effective as antianginal agents, but dipyridamole now has a role in preventing platelet aggregation and is used prophylactically for the treatment of cerebral ischemic attacks [59]. Because of the "coronary steal" phenomenon, dipyridamole has been used as a diagnostic agent for patients with coronary artery disease [60].

According to animal studies, the maximum dilatation of the coronary bed with chromonar or dipyridamole prevents normal coronary autoregulation. In addition, the enhancement of

blood flow to the subepicardial region produces a reverse redistribution, which can exacerbate subendocardial ischemia [61].

Dipyridamole [*58-32-2*], 2,2′,2″,2‴-(4,8-dipiperidinopyrimido[5,4-*d*]pyrimidine-2,6-diyldinitrilo)tetraethanol, $C_{24}H_{40}N_8O_4$, M_r 504.62, *mp* 163 °C, is treated in more detail under → Cardiovascular Drugs,

Chromonar [*655-35-6*], [[3-[2-(diethylamino)-ethyl]-4-methyl-2-oxo-2*H*-1-benzopyran-7-yl]-oxy] acetic acid ethyl ester, coumadin, $C_{20}H_{27}NO_5$, M_r 361.42, *mp* 159 – 160 °C; for its preparation, see [62].

Trade Names (hydrochloride). Antiangor (I.S.O.M., Milano), Intenkordin (Polfa), Intensain (Cassella-Riedel).

1. Introduction [1–4]

The respiratory tract is an integrated system in terms of anatomy and function. Ailments of the respiratory tract are among the most frequent diseases and tend to affect the whole airway system.

Cough is a normal physiological response to an irritation in the laryngeal–tracheal–bronchial system; it may be caused by a pathogen or by mechanical or chemical stimulation, and is vital in expelling mucus secreted in response to these stimuli. Therefore, normal and productive cough, which is useful to the patient and needs no treatment, is distinguished from nonproductive cough, which can be painful and fatiguing and should be suppressed by antitussive drugs.

Cough remedies are also used as concomitant therapy in a variety of respiratory tract diseases in which cough is a problem. These range from sore throat to more serious complaints such as bronchitis, pneumonia, and asthma.

In the treatment of whooping cough caused by *Bordatella pertussis* infection, antitussives only alleviate paroxysmal coughing.

Symptomatic cough therapy is directed at either suppressing reflex stimulation of the cough center by administering *antitussives* (Chap. 2) or promoting the removal of mucus with *expectorants* (Chap. 3). *Bronchospasmolytics* are used in patients with bronchospasm (→ Antiasthmatic Agents) and *sympathomimetics* help to shrink swollen mucous membranes in cases of inflammation.

The etiology of respiratory tract diseases is often very complex and frequently requires therapy with a combination drug. Expectorants may be combined with bronchospasmolytics, but not with antitussives because this would suppress the cough reflex and the excessive mucus could not be expelled.

Antihistamines are major ingredients of many cough preparations (→ Antiallergic Agents). In addition to their antisecretory effect, antihistamines may have a beneficial effect on allergy-induced coughing; however, they have no antitussive effect of their own.

2. Antitussives

2.1. Antitussives Acting on the Central Nervous System

Antitussives chiefly act on the central nervous system (CNS). They reduce the number and in-

tensity of coughing bouts by inhibiting the cough reflex in the cough center of the brain stem or by blocking sensitive receptors in the bronchi.

Morphine, codeine, and narcotine, isolated from opium (→ Alkaloids), were the first compounds of this group to be used. In addition to their analgesic effect, these drugs also have an antitussive potency.

Morphine is not suited for use as an antitussive because of its adverse effects (respiratory depression, constipation, addictive potential). Its analgesic potency and side effects were attenuated by etherifying its phenolic hydroxyl group (→ Analgesics and Antipyretics), but its antitussive potency was not affected by this substitution.

The methyl ether codeine is the most popular antitussive. Other morphine ethers have also been used as antitussives (e.g., ethylmorphine or pholcodine).

Chemical modification of the morphine nucleus has led to derivatives of greater analgesic and antitussive activity, but these derivatives still have morphine-like side effects (e.g., dihydrocodeine or hydrocodone). Total synthesis of the morphine skeleton by Grewe in 1946 made the morphinans accessible; their (+)-isomers are potent antitussives that do not lead to addiction.

2.1.1. Alkaloids and Derivatives
(→ Alkaloids)

Codeine [*76-57-3*], $C_{18}H_{21}NO_3$, M_r 299.36; monohydrate [*6059-47-8*], M_r 317.38, *mp* 154–156 °C, $[\alpha]_D^{15}$ −136° (*c* = 2; ethanol); hydrochloride dihydrate [*1422-07-7*], $C_{18}H_{22}ClNO_3 \cdot 2\,H_2O$, M_r 371.9, *mp* 280 °C, $[\alpha]_D^{22}$ −108° (H_2O); phosphate [*52-28-8*], $C_{18}H_{24}NO_7P$, M_r 397.38; sulfate [*1420-53-7*], $C_{36}H_{44}N_2O_{10}S$, M_r 696.82.

Codeine occurs naturally in opium (0.3 %), but most of it is prepared by methylation of morphine with trimethylphenylammonium hydroxide [5]:

Trade Names. Codicept (Sanol), Codeinfos (Union Quimico-Farmaceutica), Tricodein (Solco, Zyma), Codipertussin (Taeschner); combinations: Codipront (Mack), Tussoretard (Klinge), Codicaps (Thiemann), Empracet (Burroughs Wellcome), Copavin (Lilly), and many others.

Ethylmorphine [*76-58-4*], codethyline, dionin, $C_{19}H_{23}NO_3$, M_r 313.38, *mp* 199–201 °C; hydrochloride dihydrate [*125-30-4*], $C_{19}H_{24}ClNO_3 \cdot 2\,H_2O$, *mp* 123 °C (decomp.).

Ethylmorphine is prepared by ethylation of morphine with ethyl benzenesulfonate in the presence of potassium hydroxide [6]. The pharmacological effects of ethylmorphine are very similar to those of codeine; ethylmorphine is slightly less effective as an antitussive [7].

Trade Names. Codethyline (Houdé), Trachyl (Beytout); combinations: Expectorans Solucampher (Delalande), Tussedat (Sagitta).

Pholcodine [*509-67-1*], 3-*O*-(2-morpholinoethyl)morphine, $C_{23}H_{30}N_2O_4$, M_r 398.49, *mp* 91 °C (monohydrate), $[\alpha]_D^{20}$ −95.3° (*c* = 2; ethanol).

For the synthesis of pholcodine, morphine is alkylated with *N*-(2-chloroethyl)morpholine in the presence of sodium hydroxide [8]. Pholcodine is a centrally acting antitussive of similar potency as codeine; it has minimal side effects and no addictive potential [9].

Trade Names. Ethnine (Allen and Hanburys, Purdue Frederick), Folcodan (L.I.B.S.), Memine (Macfarlan Smith), Tussokon (Pharmacia).

Dihydrocodeine [*125-28-0*], drocode, $C_{18}H_{23}NO_3$, M_r 301.37, *mp* 112–113 °C; hydrogen tartrate [*5965-13-9*], $C_{22}H_{29}NO_9$, M_r 451.5, *mp* 192–193 °C.

Dihydrocodeine is made by catalytic hydrogenation of codeine over platinum, palladium, or nickel catalysts [10], or by methylation of dihydromorphine with dimethyl sulfate [11]. Dihydrocodeine has antitussive and analgesic properties similar to those of morphine, with fewer side effects [6], [12].

Trade Names. Paracodin (Knoll), Remedacen (MüllerRorer), Rikodeine (Riker), Tiamon (Temmler; combination).

Hydrocodone [*125-29-1*], dihydrocodeinone, $C_{18}H_{21}NO_3$, M_r 299.38, *mp* 198 °C; hydrochloride hydrate [*25968-91-6*], $C_{18}H_{22}ClNO_3 \cdot H_2O$, M_r 353.83, *mp* 185 – 186 °C (decomp.), $[\alpha]_D^{27}$ – 130° (H_2O); bitartrate hemipentahydrate [*34195-34-1*], $C_{22}H_{27}NO_9 \cdot 2.5\,H_2O$, M_r 494.5.

For the synthesis of hydrocodone, codeine is catalytically rearranged by heating with palladium or platinum in alcoholic or aqueous acidic solution [13]. For other methods of preparation, see [3, vol. 1, p. 120]. Hydrocodone is a stronger antitussive and analgesic than codeine, but it also has morphine-like side effects and addictive potential [6].

Trade Names. Dicodid (Knoll), Didrate (Penick), Novocodina (Erba); numerous combinations.

Noscapine [*128-62-1*], narcotine, (3 *S*)-6,7-dimethoxy-3-[(1 *R*)-1,2,3,4-tetrahydro-8-methoxy-2-methyl-6,7-methylenedioxy-1-isoquinolyl]phthalide, $C_{22}H_{23}NO_7$, M_r 413.43, *mp* 176 °C; hydrochloride monohydrate [*912-60-7*], $C_{22}H_{24}ClNO_7 \cdot H_2O$, M_r 467.9, *mp* 200 °C (decomp.).

Noscapine is a phthalide alkaloid which occurs in amounts up to about 6 % in opium. It is a centrally acting antitussive of nearly the same potency as codeine, but without morphine-like side effects and with additional bronchodilatory activity [14].

Trade Names. Capval (Dreluso), Lyobex (Lappe), Narcotussin (Biologici, Italia), Tusscapine (Fisons); combinations:Tussoretard (Klinge), Tiamon (Temmler), and many others.

2.1.2. Morphinans

Dextromethorphan [*125-71-3*], (+)-3-methoxy-*N*-methylmorphinan, $C_{18}H_{25}NO$, M_r 271.41; hydrobromide monohydrate [*6700-34-1*], $C_{18}H_{26}BrNO \cdot H_2O$, M_r 370.34, *mp* 122 – 124 °C, $[\alpha]_D^{20}$ +27.6° (c = 1.5; H_2O).

Dextromethorphan is made by resolution of (±)-3-hydroxy-*N*-methylmorphinan (racemorphan; → Analgesics and Antipyretics) with D-tartaric acid and subsequent O-methylation of the (+)-isomer with phenyltrimethylammonium hydroxide [15]. Dextromethorphan has an antitussive effect similar to that of codeine with fewer side effects; it does not lead to addiction [16].

Trade Names. Romilar (Hoffmann-La Roche), Cosylan (Parke-Davis), Dormethan (Dorsey), Husmedin (Toho), Methorcon (Kowa); numerous combinations.

Dimemorfan [*36309-01-0*], 3,17-dimethylmorphinan, $C_{18}H_{25}N$, M_r 255.41, *mp* 90 – 93 °C; phosphate, $C_{18}H_{28}NO_4P$, M_r 353.41, *mp* 267 – 269 °C, $[\alpha]_D^{23}$ +25.7° (c = 0.5; methanol).

Dimemorfan is prepared by using Grewe's morphinan synthesis [17]. It is 1.5 times as potent an antitussive as dextromethorphan, with some analgesic activity and minimal side effects [18].
Trade Names. Astomin (Yamanouchi), Dastosin (Morrith).

2.1.3. Arylalkylamines

Normethadone [*467-85-6*], 6-(*N,N*-dimethylamino)-4,4-diphenyl-3-hexanone, $C_{20}H_{25}NO$, M_r 295.42, *bp* 164 – 167 °C (0.4 kPa); hydrochloride [*847-84-7*], $C_{20}H_{26}ClNO$, M_r 331.88, *mp* 174 – 175 °C.

Normethadone is prepared by the same route used for methadone (→ Analgesics and Antipyretics, Chap. 3.1.3.) [19]. Normethadone is twice as potent an antitussive as codeine, but it has reduced analgesic potency compared with methadone, which is also a potent antitussive [20]. Both drugs are rarely used because of their addictive potential.
Trade Name. Ticarda (Hoechst).

Levopropoxyphene [*2338-37-6*], (−)-1-benzyl-3-(*N,N*-dimethylamino)-2-methyl-1-phenylpropylpropionate, $C_{22}H_{29}NO_2$, M_r 339.48, *mp* 75 –76 °C, $[\alpha]_D^{25}$ − 68.2° (*c* = 0.6; chloroform); 2-naphthalenesulfonate monohydrate (napsylate) [*55557-30-7*], $C_{22}H_{29}NO_2 \cdot C_{10}H_8O_3S \cdot H_2O$, M_r 565.72.

Levopropoxyphene is prepared as described for propoxyphene (→ Analgesics and Antipyretics), using the (−)-form of the intermediates [21]. Levopropoxyphene has useful antitussive properties, whereas analgesic activity is present mainly in dextropropoxyphene [22].
Trade Names. Novrad (Lilly), Sotorni (Ravensberg).

Tipepidine [*5169-78-8*], 3-(di-2-thienylmethylene)-1-methylpiperidine, $C_{15}H_{17}NS_2$, M_r 275.45, *mp* 64 – 65 °C; citrate monohydrate [*5169-77-7*], $C_{21}H_{25}NO_7S_2 \cdot H_2O$, M_r 485.58, *mp* 138 – 139 °C; 4-hydroxybenzophenone-2-carboxylate (hibenzoate) [*31139-87-4*], $C_{29}H_{27}NO_4S_2$, M_r 517.67, *mp* 187 – 190 °C. Grignard reaction of ethyl 1-methyl-3-piperidinecarboxylate (ethyl 1-methylnipecotate) with 2-thienylmagnesium bromide and acid dehydration of the intermediate carbinol yields tipepidine [23]:

Tipepidine is approximately equipotent to codeine in antitussive activity, but less analgesic and toxic [24].
Trade Names. Asverin (Tanabe), Sotal (G. Ramon).

Clofedanol [*791-35-5*], chlophedianol, 1-(2-chlorophenyl)-1-phenyl-3-dimethylaminopropanol, $C_{17}H_{20}ClNO$, M_r 289.80; hydrochloride [*511-13-7*], $C_{17}H_{21}Cl_2NO$, M_r 326.26, *mp* 190 – 191 °C. For the synthesis of clofedanol, 2-chlorobenzophenone reacts with acetonitrile in the presence of sodium amide; the nitrile group of the product is then catalytically reduced to the primary amine, and the intermediate is converted into clofedanol by reductive *N*-methylation [25]:

Clofedanol

Clofedanol is a centrally acting antitussive without analgesic activity or morphine-like side effects, but with some of the effects of a local anesthetic [26].

Trade Names. Detigon (Bayer), Pectolitan (Kettelhack Riker), Ulo (Riker), Coldrin (Nippon Shinyaku).

Clobutinol [*14860-49-2*], 2-(4-chlorobenzyl)-4-dimethylamino-3-methyl-2-butanol, $C_{14}H_{22}ClNO$, M_r 255.79, *bp* 179 – 181 °C (1.6 kPa); hydrochloride [*1215-83-4*], $C_{14}H_{23}Cl_2NO$, M_r 292.25, *mp* 169 – 170 °C. Clobutinol is made by Grignard reaction of 4-dimethylamino-3-methyl-2-butanone with 4-chlorobenzylmagnesium chloride [27].

Clobutinol

Clobutinol is an antitussive with CNS activity which is equipotent to codeine and has properties similar to those of clofedanol [28].

Trade Name. Silomat (Thomae, Badrial, Morishita).

Isoaminile [*77-51-0*], 4-dimethylamino-2-isopropyl-2-phenylvaleronitrile, $C_{16}H_{24}N_2$, M_r 244.37, *bp* 138 – 146 °C (0.4 kPa); citrate [*126-10-3*], $C_{22}H_{32}N_2O_7$, M_r 436.62, *mp* 63 – 64 °C. For the synthesis of isoaminile, benzyl cyanide is alkylated in two steps, first by isopropyl bromide and then by 2-(dimethylamino)propyl chloride in the presence of sodium amide [29].

Isoaminile

Isoaminile is similar to codeine, but it has no analgesic activity or morphine-like side effects [30].

Trade Names. Peracon (Kali-Chemie), Dimyril (Fisons).

2.1.4. Basic Esters

Butethamate [*14007-64-8*], 2-diethylaminoethyl 2-phenylbutyrate, $C_{16}H_{25}NO_2$, M_r 263.37, *bp* 167 – 169 °C (1.5 kPa), n_D^{20} 1.4909; citrate [*13900-12-4*], $C_{22}H_{33}NO_9$, M_r 455.51, *mp* 109 – 110 °C. Butethamate is made by alkylation of benzyl cyanide with ethyl bromide in the presence of sodium amide; subsequent hydrolysis of the nitrile group yields 2-phenylbutyric acid, which is then esterified by reaction of the sodium salt with 2-diethylaminoethyl chloride [31].

Butethamate

In addition to its antitussive activity, butethamate is active as a bronchodilator [32].

Trade Name. Pertix (Hommel); in many combination drugs.

Butamirate [*18109-80-3*], 2-(2-diethylaminoethoxy)ethyl 2-phenylbutyrate, $C_{18}H_{29}NO_3$, M_r 307.44, *bp* 140 – 155 °C (0.13 kPa); citrate [*18109-81-4*], $C_{24}H_{37}NO_{10}$, M_r 499.57, *mp* 75 °C. For the synthesis of butamirate, 2-phenylbutyric acid (prepared as described for

butethamate) is esterified by reaction of its acid chloride with 2-(2-diethylaminoethoxy)ethanol [33].

Compared to butethamate, the antitussive activity of butamirate is increased because of the lengthening of the side chain.

Trade Names. Acodeen (Hommel), Sinecod (Hommel, Karlspharma), Intussin (Spofa).

Pentoxyverine [*77-23-6*], carbetapentane, 2-(2-diethylaminoethoxy)ethyl 1-phenyl-1-cyclo-pentanecarboxylate, $C_{20}H_{31}NO_3$, M_r 333.46, *bp* 165 – 170 °C (0.001 kPa); citrate [*23142-01-0*], $C_{26}H_{39}NO_{10}$, M_r 525.60, *mp* 93 °C. Pentoxyverine is made by alkylation of benzyl cyanide with 1,4-dibromobutane in the presence of sodium amide; subsequent hydrolysis of the nitrile group gives 1-phenylcyclopentanecarboxylic acid, which is then esterified in a procedure analogous to that used for butamirate [34].

Pentoxyverine is more active than codeine; it has a low toxicity and shows no adverse side effects [35].

Trade Names. Atussil (Squibb), Germapect (Thiemann), Sedotussin (UCB), Toclase (Pfizer, Sumitomo), Tuclase (UCB).

Oxeladin [*468-61-1*], 2-(2-diethylaminoethoxy)ethyl 3-phenyl-3-pentanecarboxylate, $C_{20}H_{33}NO_3$, M_r 335.47, *bp* 140 °C (0.015 kPa); citrate [*16485-39-5*], $C_{26}H_{41}NO_{10}$, M_r 527.61, *mp* 90 – 91 °C. For the synthesis of oxeladin, 2-ethyl-2-phenylbutyric acid (prepared in the same way as phenylbutyric acid, see butamirate) is condensed with bis(2-chloroethyl) ether in the presence of sodium hydroxide, and the product is subsequently treated with diethylamine [36].

The pharmacological properties of oxeladin are very similar to those of pentoxyverine [37].

Trade Names. Dorex (Woelm), Paxeladine (Beaufour), Pectamol (British Drug Houses, Malesci), Hihustan (Maruko).

Dimethoxanate [*477-93-0*], 2-(2-dimethylaminoethoxy)ethyl phenothiazine-10-carboxylate, $C_{19}H_{22}N_2O_3S$, M_r 358.48; hydrochloride [*518-63-8*], $C_{19}H_{23}ClN_2O_3S$, M_r 394.91, *mp* 161 – 163 °C (decomp.).

Synthesis: phenothiazine-10-carbonyl chloride is obtained by the reaction of phenothiazine with phosgene and then converted to dimethoxanate with 2-(2-dimethylaminoethoxy)ethanol as described for butamirate [38]. Dimethoxanate is a slightly less active antitussive than codeine and shows additional local anesthetic and mucolytic effects [39].

Trade Names. Cotrane (Clin Midy), Cothera (Ayerst), Perlatos (Farmacologico Mil.).

Pipazethate [*2167-85-3*], 2-(2-piperidinoethoxy)ethyl-10*H*-pyrido[3,2-*b*][1,4]benzo-

thiadiazine-10-carboxylate, pipazetate, $C_{21}H_{25}N_3O_3S$, M_r 399.52; hydrochloride [*6056-11-7*], $C_{21}H_{26}ClN_3O_3S$, M_r 435.98, *mp* 160 – 161 °C.

Pipazethate is prepared analogously to dimethoxanate [40]. Pipazethate is predominantly a centrally acting antitussive, similar to dimethoxanate [41].

Trade Names. Selvigon (Homburg, Galenika, Panchemie), Theratuss (Squibb).

2.1.5. Basic Ethers

Benproperine [*2156-27-6*], 1-[1-(2-benzylphenoxy)-2-propyl]piperidine, $C_{21}H_{27}NO$, M_r 309.43, *bp* 159 – 161 °C (0.03 kPa); phosphate [*3563-76-6*], $C_{21}H_{30}NO_5P$, M_r 407.45, *mp* 150 – 152 °C.

Synthesis: 2-benzylphenol is converted into 1-(2-benzylphenoxy)-2-propanol with propylene oxide; the hydroxyl group of the product is then replaced by chloride or the tosyloxy group and finally by the piperidino group to give benproperine [42].

In addition to its activity on the central nervous system, benproperine also has a peripheral mode of action [43].

Trade Names. Blascorid (Pharmacia, Guidotti), Flaveric (Taito Pfizer), Pectipront (Mack), Tussafug (Robugen, Medipharm).

Cloperastine [*3703-76-2*], 1-[2-[α-(4-chlorophenyl)benzyloxy]ethyl]piperidine, $C_{20}H_{24}ClNO$, M_r 329.88, *bp* 172 – 174 °C (0.01 kPa); hydrochloride, $C_{20}H_{25}Cl_2NO$, M_r 366.31, *mp* 147.9 °C. Synthesis: 4-chlorobenzhydrol is condensed with *N*-(2-chloroethyl)piperidine in the presence of sodium amide [44].

Cloperastine is an antitussive that acts on the central nervous system with nearly the same potency as codeine but with additional antihistaminic and spasmolytic effects [45].

Trade Names. Hustazol (Yoshitomi), Seki (Simes).

Morclofone [*31848-01-8*], 4′-chloro-3,5-dimethoxy-4-(2-morpholinoethoxy)benzophenone, $C_{21}H_{24}ClNO_5$, M_r 405.88, *mp* 91 – 92 °C. Synthesis: 4-chloro-3,5-dimethoxy-4-hydroxybenzophenone is condensed with *N*-(2-chloroethyl)morpholine in the presence of sodium methoxide [46].

Morclofone is a non-narcotic antitussive with a potency similar to that of codeine [47].

Trade Names. Medicil (Medici), Nitux (Inpharzam), Plausitin (Carlo Erba).

2.1.6. Piperazine Derivatives

Dropropizine [*17692-31-8*], 3-(4-phenyl-1-piperazinyl)-1,2-propanediol, $C_{13}H_{20}N_2O_2$, M_r 236.31, *mp* 105 °C; hydrochloride, $C_{13}H_{21}ClN_2O_2$, M_r 272.78, *mp* 142 °C. Dropropizine is made by reaction of *N*-phenylpiperazine with oxiranylmethanol [48].

Dropropizine

Dropropizine is nearly as potent an antitussive as codeine and has no adverse side effects [49].

Trade Names. Catabex (Bios-Coutelier), Ribex (Formenti), Larylin (Beiersdorf; combination).

Eprazinone [*10402-90-1*], 3-[4-(β-ethoxy-2-phenethyl)-1-piperazinyl]-2-methylpropiophenone, $C_{24}H_{32}N_2O_2$, M_r 380.53, *mp* 160 °C; dihydrochloride [*10402-53-6*], $C_{24}H_{34}Cl_2N_2O_2$, M_r 453.46. Synthesis: styrene is treated with *tert*-butyl hypobromite in ethanol to give 2-ethoxy-2-phenylethyl bromide, which is then converted into eprazinone by exchange of bromine with piperazine and subsequent Mannich reaction with propiophenone and paraformaldehyde [50].

Eprazinone

In addition to its antitussive activity, eprazinone has mucolytic potency [51].

Trade Names. Eftapan (Merckle), Mucitux (Rion, Recordati), Resplen (Chugai).

Zipeprol [*34758-83-3*], 1-methoxy-3-[4-(β-methoxyphenethyl) piperazin-1-yl]-1-phenylpropan-2-ol, $C_{23}H_{32}N_2O_3$, M_r 384.52, *mp* 83 °C; dihydrochloride [*34758-84-4*], $C_{23}H_{34}Cl_2N_2O_3$, M_r 457.45, *mp* 231 °C. Zipeprol is made by the reaction of **1** with **2**, both of which are obtained in the manner described for eprazinone; the starting material for **1** is 3-phenylallyl alcohol [52].

Zipeprol

The pharmacological profile of zipeprol is similar to that of eprazinone [53].

Trade Names. Mirsol (Mepha), Respilene (Rete-France, Organon, Winthrop).

2.1.7. Other Compounds

Fominoben [*18053-31-1*], 3′-chloro-2′-{*N*-methyl-*N*-[(morpholinocarbonyl)methyl]-aminomethyl}benzanilide, $C_{21}H_{24}ClN_3O_3$, M_r 401.89, *mp* 122.5 – 123 °C; hydrochloride [*18053-32-2*], $C_{21}H_{25}Cl_2N_3O_3$, M_r 438.36, *mp* 206 – 208 °C (decomp.). Synthesis: 3-chloro-2-methylaniline is acylated with benzoyl chloride to give the *N,N*-dibenzoylamine, which is then brominated with *N*-bromosuccinimide and subsequently converted with sarcosine morpholide into fominoben with elimination of one benzoyl group [54].

Fominoben

Fominoben has the same antitussive potency as codeine but no analgesic properties or morphine-like side effects. In contrast to the structurally related bromhexine (see Section 3.2.2), it shows no secretolytic or broncholytic activity [55].
Trade Names. Noleptan (Thomae), Deronyl (VEB Radebeul), Terion (Lusofarmaco).

Sodium dibunate is a mixture of the sodium salts of 3,7- and 3,6-di-*tert*-butyl-1-naphthalenesulfonic acid (dibunate, $C_{18}H_{24}O_3S$, M_r 319.45, *mp* 158 °C); the sodium salt [*14992-59-7*], $C_{18}H_{23}NaO_3S \cdot 2\,H_2O$, M_r 360.46, melts at 300 °C (decomp.).

Dibunate is obtained by sulfonation of 2,7-di-*tert*-butylnaphthalene with chlorosulfuric acid. The reaction is accompanied by partial rearrangement of one *tert*-butyl group [56]. Dibunate was originally developed as a surfactant and is structurally unrelated to any other antitussive. It has a safe and effective antitussive action, predominantly on the central nervous system [57].
Trade Names. Becantex (Labaz), Bechisan (Sidus); combinations: Aspekton (Krewel), Makatussin (Makara).

2.2. Antitussives Acting Mainly Peripherally

Several antitussive drugs have been claimed to act predominantly on the peripheral nervous system. Theoretically this could be achieved by selective anesthetic action on either the cough receptors outside the central nervous system or the pulmonary stretch receptors. These receptors, found in the parenchyma of the lungs, are also responsible for regulating respiratory mechanisms (Hering – Breuer reflex). Therefore, the structure of this group of antitussives somewhat resembles that of local anesthetics. In addition to the peripheral activity, some smaller centrally active component may contribute to the overall effect.

Benzonatate [*104-31-4*], 3,6,9,12,15,18,21,24,27-nonaoxaoctacosyl 4-butylaminobenzoate, $C_{30}H_{53}NO_{11}$, M_r 603.73.

Synthesis: ethyl 4-butylaminobenzoate is transesterified with nonaethyleneglycol monomethyl ether in the presence of catalytic amounts of sodium methoxide [58]. Benzonatate acts mainly on the peripheral nervous system, with a small activity on the central nervous system. The selective anesthetic action on the pulmonary stretch receptors is achieved by combining a local anesthetic moiety, related to tetracaine, with a lipid-soluble side chain [59].
Trade Name. Tessalon (Ciba-Geigy, Endo).

Oxolamine [*959-14-8*], 5-(2-diethylaminoethyl)-3-phenyl-1,2,4-oxadiazole, $C_{14}H_{19}N_3O$, M_r 245.32, *bp* 127 °C (0.05 kPa); hydrochloride, $C_{14}H_{20}ClN_3O$, M_r 281.79, *mp* 153 – 154 °C; citrate [*1949-20-8*], $C_{20}H_{27}N_3O_8$, M_r 437.85. Acylation of benzamidoxime with 3-chloropropionyl chloride and subsequent cyclocondensation of the product with diethylamine yields oxolamine [60].

Oxolamine

Oxolamine acts mainly on the peripheral nervous system, with a smaller activity on the central nervous system. Additional analgesic and anti-inflammatory effects may contribute to its overall potency which is comparable to that of codeine [61].
Trade Names. Bredon (Organon), Broncatar (Pulitzer), Perebron (Angelini).

3. Expectorants [62]

Expectorants are substances that aid or accelerate the removal of bronchial secretions from the bronchi and trachea. The group of expectorants

can be divided, though not strictly, into secretolytics, mucolytics, and secretomotorics.

Secretolytics are intended to liquefy the mucus by promoting secretion. Mucolytics modify the physicochemical properties of the mucus, particularly its viscosity. Secretomotorics facilitate the passage and expulsion of secretion.

3.1. Secretolytics and Secretomotorics

Various groups of substances increase bronchial secretion. These consist of inorganic salts (in particular, ammonium chloride, calcium citrate, and potassium iodide); ipecac (dried rhizomes and roots of ipecacuanha) and emetine, which are isolated from ipecacuanha roots; and some saponin-containing drugs, such as senega root, primula rhizome, and licorice root.

Some volatile oils have secretolytic effects and, because they stimulate bronchial ciliary movement, also have secretomotor activity. They include the essential volatile oils of anise, eucalyptus, myrthe, thyme, and turpentine. Terpin hydrate [*2451-01-6*] and pinol hydrate (sobrerol) [*498-71-5*] are derived from turpentine oil.

Phenolic compounds, such as cresol and guaiacol, are also secretomotorics. However, because these compounds are severely irritating their ethers or esters are preferred in therapy. Important examples are guaiacol glycerol ether (guaifenesin), guaiacol phenylacetate, and guaiacol acetylsalicylate (guacetisal [*55482-89-8*]). Sulfoguaiacol [*78247-49-1*] is used in many combination drugs; it is a mixture of the potassium salts of 4- and 5-guaiacolsulfonic acid.

Guaifenesin [*93-14-1*], 3-(2-methoxyphenoxy)-1,2-propanediol, $C_{10}H_{14}O_4$, M_r 198.21, *mp* 78.5 – 79 °C, is made by the reaction of guaiacol with oxiranylmethanol (a) or with 3-chloro-1,2-propanediol (b) in the presence of sodium hydroxide [63].

Guaifenesin increases and promotes the secretions of the respiratory tract by acting directly on the secretory cells [64]. It is also a centrally active muscle relaxant.

Trade Names. Resyl (Ciba-Geigy), Robitussin (Robins, Scheurich) and many others; numerous combination drugs.

3.2. Mucolytics

Mucolytics consist of several groups of substances with different mechanisms of action. *Surfactants* reduce surface tension; therefore, they lower the viscosity and facilitate the removal of viscid secretions.

The most popular compound of this type is *tyloxapol* [*25301-02-4*], Triton WR 1339, a polymer of 4-isooctylpolyoxyethylene-2-cresyl ether.

Trade Names. Alevaire (Winthrop, Breon, Berger), Tacholiquin (Bene-Chemie).

Cysteine derivatives have the greatest effect on mucus viscosity. Their reactive thiol groups probably cleave the disulfide bridges of mucoproteins.

The *benzylamines* bromhexine and ambroxol (Section 3.2.2) are structurally derived from the alkaloid vasicine. They have both mucolytic and secretolytic effects.

3.2.1. Cysteine Derivatives

Acetylcysteine [*616-91-1*], *N*-acetyl-L-cysteine, $C_5H_9NO_3S$, M_r 163.20, *mp* 109 – 110 °C, is made by acylating L-cysteine hydrochloride hydrate with acetic anhydride in the presence of sodium acetate [65]. Acetylcysteine is an effective mucolytic in vitro and in vivo, especially when administered as an aerosol [60], [66].

Trade Names. Fluimucil (Arsac, Inpharzam, Zambon), Fabrol (Ciba-Geigy), Mucomyst (Mead Johnson, Allard, Astra).

Carbocysteine [*638-23-3*], *S*-carboxymethyl-L-cysteine, $C_5H_9NO_4S$, M_r 179.21, *mp* 204–207 °C, is made by *S*-alkylation of L-cysteine with chloroacetic acid in the presence of sodium hydroxide [67]. Carbocysteine decreases bronchial secretion and promotes expulsion. It has no free sulfhydryl group and is therefore administered only orally (to induce metabolic activation) and not by aerosol [60], [68].

Trade Names. Lisomucil (Lirca), Mucodyne (USV, Berk), Mucopront (Mack), Rhinathiol (Joullié), Transbronchin (Homburg).

Mecysteine hydrochloride [*18598-63-5*], methyl L-cysteinate hydrochloride, $C_4H_{10}ClNO_2S$, M_r 171.66, *mp* 140–141 °C, $[\alpha]_D^{20}$ −2.9° (10 %; methanol), is made either by esterifying L-cysteine hydrochloride monohydrate with methanolic hydrochloric acid or by reducing L-cystine dimethyl ester dihydrochloride catalytically or with zinc and hydrochloric acid [69].

Trade Names. Acthiol (Joullié), Actiol (Lirca), Epecoale (Beppu), Visclair (Sinclair).

Letosteine [*53943-88-7*], 2-[2-(ethoxycarbonylmethylthio)ethyl]-1,3-thiazole-4-carboxylicacid, $C_{10}H_{17}NO_4S_2$, M_r 279.37, *mp* 142 °C, is made by treating ethyl mercaptoacetate with acrolein to give ethyl 3-oxopropylthioacetate, which is then condensed with L-cysteine [70]. For its pharmacological properties, see [71].

Trade Name. Viscotiol (Erba, ISF).

Mesna [*19767-45-4*], sodium 2-mercaptoethanesulfonate, $C_2H_5NaO_3S_2$, M_r 164.17, is made by S-alkylation of thiourea with 2-bromoethanesulfonic acid and cleavage of the isothiourea group with sodium hydroxide [72]. For its pharmacological properties, see [73].

Trade Names. Mistabronco (UCB), Mucofluid (UCB).

3.2.2. Benzylamines

Bromhexine, *N*-cyclohexyl-*N*-methyl-*N*-(2-amino-3,5-dibromobenzyl)amine [*3572-43-8*], $C_{14}H_{20}Br_2N_2$, M_r 376.16; hydrochloride [*611-75-6*], $C_{14}H_{21}Br_2ClN_2$, M_r 416.62, *mp* 237.5–238 °C, is made by alkylating *N*-methylcyclohexylamine with 2-nitrobenzyl bromide to give *N*-methyl-*N*-(2-nitrobenzyl)cyclohexylamine, which is subsequently converted into bromhexine by reduction of the nitro group with hydrazine and Raney nickel, followed by bromination [74]. Bromhexine increases the amount of respiratory tract fluid and reduces its viscosity by activating enzymes that hydrolyze mucopolysaccharides [62], [75].

Trade Names. Bisolvon (Thomae, Boehringer Ingelheim, Badrial, Bender, Tanabe), Auxit (Heyden); many combinations.

Ambroxol [*18683-91-5*], *trans*-4-[(2-amino-3,5-dibromobenzyl)amino]cyclohexan-

ol, $C_{13}H_{18}Br_2N_2O$, M_r 378.11; hydrochloride, $C_{13}H_{19}Br_2ClN_2O$, M_r 414.58, *mp* 233 – 234.5 °C (decomp.).

Synthesis: catalytic hydrogenation of 4-acetamidophenol over rhodium catalysts and subsequent hydrolysis with sodium hydroxide yields *trans*-4-aminocyclohexanol; this is then condensed with 2-amino-3,5-dibromobenzaldehyde to give the Schiff base which is finally reduced to ambroxol with sodium tetrahydroborate or formic acid [76].

Ambroxol

Ambroxol is the active metabolite of bromhexine and, therefore, has similar pharmacological effects, but with increased bioavailability [77].

Trade Names. Mucosolvan (Thomae, Bender, De Angeli), Fluibron (Chiesi).

1. Cresols [1–3]

Cresol, methylphenol, C_7H_8O, M_r 108.14, occurs in three isomeric forms:

o-Cresol 2-methylphenol [*95-48-7*] | *m*-Cresol 3-methylphenol [*103-39-4*] | *p*-Cresol 4-methylphenol [*106-44-5*]

Mixtures of *m*- and *p*-cresol and of *o-, m-,* and *p*-cresol are occasionally referred to in the technical literature as dicresol and tri- or isocresol, respectively.

Cresylic acids [*1319-77-3*] are mixtures of cresols, xylenols, higher alkylated phenols, and possibly some phenol. *Tar acids* are cresylic acids obtained from tar.

STÄDELER first discovered cresol in cow's urine in 1851 [4]. FAIRLIE and WILLIAMSON found it in coal-tar creosote in 1854. (The word cresol, in which "creosote" and "phenol" are combined, is partly explained by this fact.) Cresol was first synthesized in 1866 by GRIESS, who boiled diazotized toluidine. All three cresol isomers were distinguished for the first time by ENGELHARDT and LATSCHINOFF in 1869.

Cresols and cresol derivatives (ethers and esters) are widely distributed in nature. They are formed as metabolites of various microorganisms and are found in the urine of mammals. Humans eliminate, on average, 87 mg of *p*-cresol per day in the urine [5]. Cresol in its various forms is also detectable in the extracts and water vapor distillates of many plants, e.g., in jasmine flower oil, cassia flower oil, easter lily oil, and ylang ylang oil, in the floral oil of *Yucca gloriosa,* in the scent of *Viola odorata,* in peppermint, eucalyptus, and camphor oil, and in the essential oils of several plants of the genus *Artemisia,* of conifers, of oak wood, and of sandalwood. Small amounts of cresol are also found in certain foods and drinks, e.g., in tomatoes and tomato ketchup, mushrooms, cooked asparagus, milk [6], certain types of cheese, butter oil, red wine, whisky, rum, cognac, and other brandies [7], raw and roasted coffee, black tea, smoked foods, and tobacco and tobacco smoke. Considerable amounts of cresol may be formed and en-

ter surface waters if forests are pyrolyzed by pyroclastic flow from erupting volcanoes, as happened after the eruption of Mount St. Helens in 1980 [8].

Cresols are important chemical raw materials. They were originally obtained only from coal tar; after World War II, they were also obtained from spent refinery caustics. Since the mid-1960s, they have been produced synthetically on an increasingly large scale. "Synthetic cresol" now provides ca. 60 % of the requirements of the United States, Europe, and Japan; only ca. 40 % of the requirements are now met by "natural cresol," i.e., cresol from coal tar and spent refinery caustics.

1.1. Physical Properties [1], [9–12]

As pure substances, *o*- and *p*-cresol are crystalline; *m*-cresol is a viscous oil at room temperature. The cresols have a phenolic odor and are colorless, but become yellow to brown after a time. Because water dissolves freely in cresols, they absorb moisture from the air.

Physical data relating to the cresols have been compiled in Tables 1 and 2. Data concerning the temperature dependence of their thermodynamic properties are found in [9–14]; many additional properties are contained in [11]; and a differential thermal analysis study is described in [15]. Thermophysical properties of *m*-cresol as a function of temperature (303 – 503 K) and pressure (0.1 – 400 MPa) are given in [16]. For the relationship between vapor pressure and association of cresols, see [17].

The solubility of the cresols in phenol and in many organic solvents, e.g., aliphatic alcohols, ethers, chloroform, and glycerol, is high. They are less soluble in water than phenol. The presence of other water-soluble organic compounds (e.g., methanol) raises their solubility in water and reduces the critical solution temperature [19]. Dissolved inorganic salts lower the water solubility of cresols.

The cresols can be distilled with steam and form azeotropes with a number of compounds, e.g., decane, 1-decene, 1-undecene, dodecane, 1,2,4,5-tetramethylbenzene, divinylbenzene, ethylene glycol, diethylene glycol methyl and ethyl ether, diethylene glycol diethyl ether, ethylene glycol diacetate, benzyl formate, phenyl acetate, methyl benzoate, hexane-2,5-dione, 2-octanone, acetophenone, benzylamine, the toluidines, and numerous pyridine derivatives. Vapor – liquid equilibrium data of the cresols with numerous other substances are compiled in [20]; those of *m*-cresol with carbon dioxide and nitrogen under pressure at 190 – 390 °C are given in [21] (2 – 5 MPa) and [22] (2 – 25 MPa), respectively.

1.2. Chemical Properties [2], [23]

Acidity. The cresols are chemically similar to phenol. They are weak acids and dissolve in aqueous alkali to form water-stable salts known as cresolates. Therefore, they can be extracted into sodium hydroxide solution from solvents that are not miscible with water. Nevertheless, their acidity is so low (pK_a 10.1 – 10.3) that even hydrogen sulfide (pK_a 7.2) and carbon dioxide (pK_a 6.4) are able to liberate them from cresolates. Thus, they hardly dissolve at all in solutions of sodium carbonate or sodium hydrogencarbonate.

Etherification and Esterification. The hydroxyl group can be etherified with alkyl halides, dialkyl sulfates, dialkyl carbonates, and toluenesulfonic acid esters, and react with acyl anhydrides or acyl chlorides to give the corresponding tolyl esters, which are normally referred to as "cresyl" esters. Isocyanates react with the OH group to form urethanes.

Substitution of the Hydroxyl Group. Under drastic conditions (420 °C, Al_2O_3), the OH group is replaced by ammonia, and the corresponding toluidine is obtained. If cresols are reacted with sulfur oxytetrafluoride at 150 °C, with diphenylphosphine trichloride at 220 °C, or with phosphorus tribromide at 280 °C, the corresponding fluoro-, chloro-, or bromotoluene is obtained. Butanethiol in hydrochloric acid replaces the phenolic OH group by a thiobutyl group. Distillation with zinc powder gives toluene.

Hydrogenation. Hydrogenation in the vapor phase at 300 – 400 °C under pressure (up to 8 MPa) in the presence of catalysts consisting of transition metals and aluminum oxide

Table 1. Physical properties of pure cresols

Property	*o*-Cresol	*m*-Cresol	*p*-Cresol
Melting point at 101.3 kPa, °C	30.99	12.22	34.69

gives toluene (hydrodeoxygenation) [24]. Hydrogenolysis over catalysts at 400 – 500 °C or purely thermally at 500 – 700 °C can be so controlled that cresol is mainly demethylated to phenol (hydrodealkylation) [25]. Hydrogenation over Raney nickel or noble-metal catalysts under less severe conditions gives methylcyclohexanones or methylcyclohexanols.

Oxidation. The cresols are sensitive to oxidation. Depending on the oxidizing agent, reaction conditions, and position of the methyl group, oxidative reactions, which occur by free radical mechanisms, lead to a large number of compounds such as hydroquinones, quinols, quinones, cyclic ketones, furans, dimeric and trimeric cresols, and tolyl ethers. Strongly oxidizing agents break down the phenol ring.

After the hydroxyl group has been protected by esterification or etherification, the methyl group can be selectively mono-, di-, or trichlorinated, or selectively oxidized to a formyl group (e.g., with manganese dioxide or oxygen) or to a carboxyl group (with acid permanganate solution). Unlike *m*-cresol, *o*- and *p*-cresol can be directly oxidized with oxygen to give *o*- and *p*-hydroxybenzaldehyde, e.g., in methanolic sodium hydroxide in the presence of catalytic amounts of iron tetraarylporphines [26]. Alkali fusion of the cresols in the presence of lead oxide or manganese dioxide produces the corresponding hydroxybenzoic acids directly.

Electrophilic Nuclear Substitution. Cresols, like phenol, readily undergo electrophilic substitution. The substituent enters the nucleus mainly in the *o*- and *p*-positions relative to the hydroxyl group. The cresols can therefore be nitrated even with dilute nitric acid. Nitrosation, halogenation, sulfonation, and alkylation occur readily. If *o*- or *p*-cresol is heated with Friedel – Crafts catalysts, such as $AlCl_3$, isomerization to *m*-cresol, thermodynamically the most stable of the three isomers (see page 16), occurs. The heating of dry alkali metal cresolates with CO_2 under pressure produces hydroxy(methyl)benzoic acids (Kolbe – Schmitt reaction). In the presence of alkali, formaldehyde adds to cresols, even at room temperature, to form hydroxy(methyl)benzyl alcohols; under acidic conditions or at elevated temperatures these condense to form high-molecular resins. The main products of the reaction of cresols with chloroform and alkali are *o*-hydroxy(methyl)benzaldehydes (Reimer – Tiemann synthesis). Electrophilic substitutions are occasionally complicated by partial or substantial cessation of the reaction at the primary stage of the cyclohexadienone formed by addition of the electrophile. Thus, if *p*-cresol is heated with tetrachloromethane in the presence of aluminum chloride, the main product is 4-methyl-4-trichloromethyl-2,5-cyclohexadienone (Zincke – Suhl reaction).

Behavior toward Materials [27]. At elevated temperature unalloyed steel is attacked by cresols to a noticeable extent, the severity of the attack depending on the water content. Stress corrosion cracking may occur even at 100 °C. Chromium steels are scarcely more resistant than unalloyed steels. Chromium – nickel stainless steels of the V2A type (AISI 321) are corroded at elevated temperatures at a rate of 0.1 – 1 mm/a, whereas the rate for V4A steels (AISI 316Ti) in boiling cresol is ca. 0.1 mm/a. Nickel is more resistant, its corrosion rate in pure cresols at 190 °C being only ca. 0.001 mm/a. Tantalum is considered to be entirely resistant to cresols.

Aluminum and its alloys are attacked severely at temperatures greater than ca. 120 °C when the water content of the cresol is too low. If the cresol contains less than ca. 0.3 % water, corrosion may proceed explosively. The use of copper and brass alloys should also be avoided.

The corrosive behavior of the cresols can alter significantly, depending on the presence of other compounds. Thus, the simultaneous presence of water-soluble chlorides and basic nitrogen compounds in the distillation of cresol/xylenol fractions has synergistic effects, leading, for example, to very severe corrosion of stainless steels [28].

Extensive experience concerning the behavior both of pure cresols and of cresols mixed with other substances toward metallic and nonmetallic materials is described in [27].

1.3. Formation and Isolation [29], [30]

In addition to phenol, cresols, xylenols, and numerous other phenols are found in the waste-

water of cracking processes [31], tars, and tar-like products (→ Tar and Pitch) formed in the purely thermal cracking (carbonization and coking, → Coal Pyrolysis) [29], [30], oxidizing thermal cracking (→ Gas Production) [29], [30], and hydrogenating thermal cracking (→ Coal Liquefaction [29], [30], Coal Pyrolysis [32]) of such natural materials as bituminous coal [33], lignite, [34], oil shale [35], peat, wood [36], lignin [37], and other biomaterials [38], [39].

The yields of cresols, xylenols, and other phenols and their quantity ratio depend not only on the starting material, but also largely on the process conditions (especially the temperature and the residence time), the type of reactor, and the mode of operation. With bituminous coal, hydrogenation provides the highest yields, low-temperature carbonization gives intermediate amounts, while high-temperature coking produces the lowest yields; gasification of lignite gives significantly more phenol, cresols, and xylenols than that of bituminous coal (Table 3).

Small amounts of cresols, xylenols, and other phenol derivatives are also formed in the catalytic and thermal cracking (especially coking thermal cracking) of petroleum fractions [40].

At the present time cresols and xylenols are isolated from coal tars obtained in the high-temperature coking process, low-temperature carbonization, and Lurgi pressure gasification of coal (see Table 3), and from spent refinery caustics.

1.3.1. Isolation from Coal Tars

A traditional source of tar cresols and xylenols, but one that has been continously declining over the past 40 years (potential ca. 30 000 – 40 000 t/a) is the high-temperature coke-oven tar (composition and work up → Tar and Pitch), obtained in the production of metallurgical coke by horizontal chamber coking of bituminous coal at 900 – 1300 °C [29]. This tar contains, on average, ca. 0.4 – 0.6 wt % phenol, 0.8 – 1 wt % cresols, and 0.2 – 0.5 wt % xylenols. In the United Kingdom, cresols are also produced from low-temperature coal tars obtained in the production of smokeless fuels (semi-coke) according to the Coalite process, where the content of $C_6 - C_8$ phenols is ca. 10 times higher. But by the 1990s these tars had become far less abundantly available. Today the largest source of "natural" cresols and xylenols (35 000 – 55 000 t/a) [41] is provided by the liquid byproducts obtained by Sasol in the pressure gasification of bituminous coal by the Lurgi process to produce synthesis gas for South Africa's three Fischer – Tropsch plants [42], which are similar in composition to low-temperature tars. In the United States the liquid coproducts from the Lurgi gasifiers of the Dakota Gasification Co., which gasifies lignite to synthetic natural gas (SNG), are an essential source of "natural" cresols and xylenols (potential ca. 5000 t/a *o*-cresol, 11 000 t/a *m*/*p*-cresol, and 10 000 t/a xylenols) [43].

When the starting material is high-temperature tar, the phenols are isolated by extraction with sodium hydroxide solution or, in the Lurgi phenoraffin process (→ Tar and Pitch), from the carbolic oil that boils at 180 – 210 °C, from the light oil, and from the filtrate of the naphthalene oil; where other coal tars are concerned the procedures are similar. The hydrocarbons and pyridine bases still present in the crude phenolate caustic are removed by distillation with steam. The crude phenol is then liberated with carbon dioxide. Frequently, the phenolate caustics from coking plant effluents, which contain primarily phenol and cresol and only very small amounts of xylenols [44], are incorporated. The composition of the resulting crude phenol may, therefore, vary extensively. For example, the composition of crude phenol obtained in this way from German high-temperature coke-oven coal tar may be as follows [33]: 15 % water, 30 % phenol, 12 % *o*-cresol, 18 % *m*-cresol, 12 % *p*-cresol, 8 % xylenols, and 5 % trimethylphenols together with higher boiling phenols.

After the alkali content of the crude phenol has been lowered from ca. 2 % to ca. 0.3 % by scrubbing with water, the crude phenol is dehydrated azeotropically and rectified under vacuum into the following fractions: phenol, *o*-cresol, *m*-/*p*-cresol mixture, xylenol, and phenol tar. As the difference between the boiling points of *m*- and *p*-cresol is very small (0.3 °C), these compounds are obtained as a single fraction in which small amounts of 2,6-xylenol and 2-ethylphenol are also present. The ratio of *m*-cresol to *p*-cresol is ca. 60 : 40 for high-temperature tar and ca. 50 : 50 for low-temperature tar.

Table 3. Average yields of phenols in the tars of various cracking processes∗

Phenol	Sump-phase hydrogenation, coal oil	Low-temperature tars	Lurgi gasifier tar	Lignite tar	High-temperature coke-oven tars (1200 – 1300 °C)		
	(ca. 470 °C)	(600 – 650 °C)	(800 – 900 °C, 20 bar)		USA	UK	FRG

Sum of cresols	26	3.1	0.63	5.0	0.31	0.39	0.24

∗ Data in kilogram of phenol per tonne of water-free bituminous coal.

The isolation of cresylic acids from the liquid coproducts obtained by gasification of North Dakota lignite [43] is possible in modifications of known industrial processes [45]. For the further purification of the cresylic acid fractions from neutral oils, tar bases, sulfur compounds, and undesirable phenolic substances (e.g., 2,6-xylenol, *o*-ethylphenol, guaiacol, and other alkoxyphenols), an extractive distillation with diethylene glycol was developed by the Dakota Gasification Co. [46].

Examples of companies that isolate cresols (and xylenols) from coal tar are Sasol Phenolics since 1993 in South Africa, the Merichem Co. in the United States in joint venture with Sasol (named Merisol) and in contract with the Dakota Gasification Co. in the United States (Dakota Gas until now only isolates phenol from the coal tars and markets the remaining crude cresylic fractions for isolation by others), Coalite Chemicals in the United Kingdom (also in contract with Dakota Gas), Rütgers-VfT AG in Germany, DEZA Corporation in the Czech Republic (works up coal tars from Eastern European countries), and in Japan the Nippon Steel Chemical Co., Sumikin Chemical Co., Kansai Distillation Co., and ADCHEMCO Corporation.

1.3.2. Recovery from Spent Refinery Caustics

In the United States, cresols and xylenols are obtained partly from the naphtha fractions produced by catalytic and thermal cracking in the petroleum industry, which contain, on the average, ca. 0.1 % $C_6 - C_8$ phenols [40], [47]. In the scrubbing of the sulfur compounds contained in these fractions (hydrogensulfides, alkyl- and arylthiols) with concentrated alkaline solutions, a process known as "sweetening," the acid cresols and xylenols are also extracted. The composition of the spent cresylate caustics fluctuates widely, and they contain on the average 20 – 25 % $C_6 - C_8$ phenols and 10 – 15 % sulfur compounds. Until around 1990 the caustics were collected by the reprocessing firms Merichem, Northwest Petrochemical, and PMC Specialties (formerly Productol), and reprocessed in central plants by a variety of processes. Because of competition, especially from synthetic *o*-cresol producers, increased environmental restrictions, and an overall lack of raw material, Northwest Petrochemical and PMC Specialties have closed their operations, and Merichem, the biggest of the three, is now the only processor of spent refinery caustics in the United States.

At Northwest Petrochemical in Anacortes, Washington, the thiols in the alkaline solution were first oxidized with air to give disulfides, which were then decanted as an oily layer [48]:

$$RSNa + R'SNa + 0.5\,O_2 + H_2O \longrightarrow RSSR' + 2\,NaOH$$

The phenols were then precipitated from the aqueous alkaline phase in a packed column with a countercurrent stream of carbon dioxide (flue gas) and decanted. The phenols still present in the carbonate – hydrogencarbonate phase (2 – 6 %) were extracted with an organic solvent, from which they are extracted again with an aqueous alkaline phase, which was then returned

to the column. A typical composition of the phenol mixture obtained in this way might be as follows: 20 % phenol, 18 % *o*-cresol, 22 % *m*-cresol, 9 % *p*-cresol, 28 % xylenol (all six isomers plus ethylphenol), and 3 % higher phenols. This mixture was then separated by distillation into phenol, *o*-cresol, *m*-/*p*-cresol mixture, and xylenols, or mixtures in which particular constituents predominate.

The Merichem Co. of Houston, Texas, precipitates the phenols with hydrogen sulfide, a waste product of the refineries in Houston [49], [50], instead of using carbon dioxide. After extraction with a solvent, the sulfide solution obtained in this process is concentrated in a triple-effect evaporator to give sodium sulfide for use in the paper industry and in ore dressing [50].

The water vapor condensate formed at this stage is stripped with natural gas to remove odorous compounds, after which it is passed to a cooling tower. The natural gas is then used as a fuel in the final process air incinerator. Before being introduced into the waste air incinerator, which is operated at ca. 1370 °C, the process air from all of the other parts of the plant is scrubbed with alkaline solution. In addition, odor-neutralizing chemicals are sprayed alongside the plant area. All of the water at the plant (including rain water) is recycled in an integrated system. Water is released into the environment almost completely as water vapor from the cooling towers [50], [51].

In the process operated until 1971 by the Pittsburgh Consolidated Chemical Co. [52], [53], the spent refinery caustics were treated directly with flue gas containing 8 – 14 % carbon dioxide. From the crude phenol thus precipitated, a fraction boiling at 100 – 235 °C was removed by distillation and extracted continuously in a countercurrent of aqueous methanol – light naphtha. After removal of the final thiol and base residues with an ion-exchange resin, the cresylic acids that had entered the aqueous methanolic phase were recovered by fractional distillation.

In 1996, the "cresylics" capacity of Merichem was ca. 55 000 t/a [54]. However, this figure includes phenol, the xylenols, and several other alkylphenols. In addition, Merichem no longer isolates cresylics exclusively from spent refinery caustics, but also works up cresylics from a variety of sources, e.g., from the coal gasification plants of Dakota Gas and Sasol.

The recovery of cresols and xylenols from spent refinery caustics has so far been confined to the United States. Because different refinery techniques are used in Germany, the production of cresol-containing spent caustics is insufficient for economical reprocessing; or no spent caustics are produced at all because desulfurization is carried out differently, e.g., by hydrotreating. In the United States as well, the recovery of cresol from spent refinery caustics is stagnating or even receding because the refineries are likewise changing over either to hydrotreating or to UOP's Merox process, partly because the price of sodium hydroxide has risen. With the Merox process, substantial quantities of cresols remain in the gasoline, and considerably smaller amounts of spent caustics are obtained.

1.4. Production

Since 1965, when the recovery of cresols from coal tar and spent refinery caustics had become insufficient to meet the rising demand, these compounds have been increasingly produced by synthesis. The processes now in use are

- Alkali fusion of toluenesulfonates
- Alkaline chlorotoluene hydrolysis
- Splitting of cymene hydroperoxide
- Methylation of phenol in the vapor phase

The first three processes start from toluene and were developed from the corresponding benzene – phenol syntheses; to some extent they are even carried out in converted plants that formerly produced phenol. In the following descriptions, attention will be primarily paid to the differences between these processes. The methylation of phenol is a process specifically developed to produce cresols and xylenols. Each process gives a different isomer distribution, and all are, therefore, of individual importance.

1.4.1. Alkali Fusion of Toluenesulfonates
[55], [56], [57]

Alkali fusion is used mainly to manufacture *p*-cresol and consists of four reaction steps:

$$2\,CH_3-C_6H_5 + 2\,H_2SO_4 \rightleftarrows 2\,CH_3-C_6H_4-SO_3H + 2\,H_2O \quad (1)$$

$$2\,CH_3-C_6H_4-SO_3H + Na_2SO_3 \longrightarrow 2\,CH_3-C_6H_4-SO_3Na + H_2O + SO_2 \quad (2)$$

$$2\,CH_3-C_6H_4-SO_3Na + 4\,NaOH \longrightarrow 2\,CH_3-C_6H_4-ONa + 2\,Na_2SO_3 + 2\,H_2O \quad (3)$$

$$2\,CH_3-C_6H_4-ONa + SO_2 + H_2O \longrightarrow 2\,CH_3-C_6H_4-OH + Na_2SO_3 \quad (4)$$

$$2\,CH_3-C_6H_5 + 2\,H_2SO_4 + 4\,NaOH \longrightarrow 2\,CH_3-C_6H_4-OH + 2\,Na_2SO_3 + 4\,H_2O$$

The sulfonation of toluene (Eq. 1) is normally carried out with concentrated sulfuric acid at 120 – 130 °C and atmospheric pressure. To ensure that substantially all of the sulfuric acid has reacted, the water of the reaction is entrained with excess toluene vapor. The sulfonic acid mixture is neutralized with sodium sulfite (and/or sodium hydroxide) (Eq. 2) and then fused with excess sodium hydroxide at 330 – 350 °C (Eq. 3). The melt is introduced into water, the sodium sulfite filtered off, and the aqueous phase acidified with sulfur dioxide from reaction step (2) and/or with sulfuric acid (Eq. 4). This gives an aqueous phase containing sodium sulfite, which is returned to the neutralization unit (2), and a crude cresol phase, which is dehydrated by azeotropic distillation. The plant and process are similar to those formerly used in the synthesis of phenol by alkali fusion of sodium benzenesulfonate. The dehydrated crude cresol phase is separated by fractional distillation into phenol, *o*-cresol, *m*-/*p*-cresol mixture, and a residue containing ditolyl sulfones, xylenols, higher phenols, and other compounds. The ditolyl sulfones are formed in the sulfonation; the phenols and xylenols are formed in small quantities in the alkali fusion [58], [59]. See [58] for the mechanism of the fusion reaction.

The distribution of the cresol isomers depends mainly on the sulfonation conditions. Normally a mixture of the following composition is obtained: 6 – 12 % *o*-cresol, 6 – 12 % *m*-cresol, 80 – 85 % *p*-cresol [55], [60]. After the *o*-cresol has been removed by distillation, a *p*-cresol of ca. 90 % purity can be obtained by distillation. From this, *p*-cresol with a *m*-cresol content of only ca. 1 % can be isolated relatively easily by melt crystallization (see Section 1.5.1).

A cresol yield of 80 %, based on toluene, is possible [60]. The yield falls as the *m*-cresol content of the cresol mixture increases [55], [59].

Under kinetically controlled (mild) sulfonation conditions and mild alkali fusion, it is possible to produce cresol mixtures with an even smaller content of *m*-cresol. It has been claimed that sulfonation with chlorosulfuric acid at 33 – 45 °C gives a product free from *m*-cresol at a yield of 90 % (calculated on the basis of toluene) and with an *o*-/*p*-cresol ratio of 15 : 85 [61]. The sulfonation of toluene with sulfur trioxide – sulfur dioxide mixtures at 25 – 50 °C likewise leads to toluenesulfonic acid mixtures almost free of the *m* isomer, and which have an *o*-/*p*-isomer ratio as low as 3 : 97 [62]. In the absence of sulfur dioxide as a solvent, it may even be possible to obtain an *o*- and *m*-isomer content of only 0.5 % when the process is carried out in a loop reactor at 0 °C, and when gaseous SO_3, diluted with an inert gas, is introduced into the reactor at several locations [63]. The inert gas (waste gas) is not necessary if the process is carried out under vacuum [64]. With oleum or sulfuric acid, *m*-free sulfonation to give mainly *p*-toluenesulfonic acid is possible if the reaction is carried out with a short residence time in a rotating film reactor [65].

Thermodynamically controlled sulfonation conditions (high temperature, long reaction time, and the use of a sulfonation mixture with a low water content) lead to an equilibrium mixture containing ca. 5 % *o*-, 54 % *m*-, and 41 % *p*-toluenesulfonic acid [66]. Alkali fusion of such mixtures then gives an isomer distribution of ca. 5 % *o*-cresol, 56 % *m*-cresol, and 39 % *p*-cresol [59].

Technical-grade *m*-cresol can also be produced by toluene sulfonation according to a process developed by the Honshu Chemical Industry Co. [67]. Steam at 165 °C is introduced into an toluenesulfonic acid mixture rich in *m* isomer obtained under thermodynamically controlled conditions as described above (isomerization for several hours at 190 – 200 °C), whereupon *o*- and *p*-toluenesulfonic acid are hydrolyzed back to sulfuric acid and toluene. The toluene is distilled with the steam; *m*-toluenesulfonic

acid with a purity above 90 % remains, together with sulfuric acid. Side reactions during the isomerization and hydrolysis can be suppressed by adding sodium sulfate (5 – 10 mol%, calculated on the basis of sulfuric acid) to the sulfonation batch. In this way, removal of the sulfuric acid that is formed in the hydrolysis as a lower phase at ca. 140 – 150 °C is also possible [68]. It is also possible to neutralize the hydrolysis mixture with concentrated sodium hydroxide solution, filter off the resulting sodium sulfate at 80 °C, introduce the solution of sodium *m*-toluenesulfonate into a sodium hydroxide melt, containing 10 – 15 % potassium hydroxide to facilitate stirring, at an initial temperature of 330 °C, and to fuse it at 340 °C.

The distillation of the crude cresol phase obtained after acidification gives *m*-cresol with a purity of up to 98 % in a yield of ca. 65 %, calculated on the basis of reacted toluene [68].

p-Cresol is produced according to the toluene sulfonation process by PMC (formerly Sherwin-Williams; capacity ca. 18 000 t/a) in the United States, by Inspec Fine Chemicals (formerly Synthetic Chemicals Ltd., now a part of Laporte; capacity ca. 12 000 t/a; sulfonating agent is SO_3) in the United Kingdom, by Beraton (capacity ca. 3000 t/a) in Russia, and in Japan by Konan Chemicals (ca. 4000 t/a). Honshu Chemical Industry Co. in Japan has a standby plant (ca. 2500 t/a) that can produce *m*- or *p*-cresol. A plant designed to operate the Honshu process is also reported to be capable of producing 3000 – 5000 t/a of *p*-cresol or *m*-cresol has been built in India by Gujarat Aromatics.

The toluenesulfonic acid – cresol process is relatively simple as regards the plant required. Its primary drawback is the unavoidable formation of sodium sulfite in aqueous solution. At Inspec Fine Chemicals, the sodium sulfite is upgraded into a product suitable for the paper industry [69]. At PMC, sodium sulfite is oxidized with air to form sodium sulfate [70], but *p*-cresol is still present in the aqueous sulfite solution (3000 – 5000 ppm); to avoid stripping, thereby causing an odor problem in the neighborhood of the plant, the solution is first passed through columns of activated carbon to adsorb the cresol. The activated carbon is regenerated every 24 h with 10 % sodium hydroxide solution. The amount of *p*-cresol recovered in this way is sufficient to pay for the additional installations [71].

1.4.2. Alkaline Chlorotoluene Hydrolysis

The hydrolysis process is important in the production of cresol with a high *m*-cresol content, and is used in Germany by Bayer AG, the world's largest manufacturer of synthetic cresols (capacity more than 30 000 t/a).

In the first reaction step, a mixture of *o*- and *p*-chlorotoluene in a 1 : 1 ratio is produced by chlorinating 1 mol of toluene with 1 mol of chlorine in the presence of iron(III) chloride and disulfur dichloride (→ Chlorinated Hydrocarbons). With $FeCl_3$ and other cocatalysts *o/p* ratios from 3 : 1 [72] to 1 : 2 [73], [74] are possible.

$$CH_3-C_6H_5 + Cl_2 \longrightarrow CH_3-C_6H_4-Cl + HCl$$

In the next reaction step, this mixture is hydrolyzed with excess sodium hydroxide solution (2.5 – 3.5 mol/mol) at 360 – 390 °C and 280 – 300 bar (28 – 30 MPa) [75].

$$CH_3-C_6H_4-Cl + 2\,NaOH \longrightarrow CH_3-C_6H_4-ONa + H_2O + NaCl$$

The exothermic reaction is carried out continuously in high-pressure tubes several hundred meters long; the tubes are made of nickel steel to withstand the corrosive action of the reaction mixture. Separation of the components, which are introduced via a mixing chamber, is prevented by causing the reaction mass to flow at high velocity, with frequent changes in the direction of flow; finally, the reaction mixture is homogeneous.

The cresol in the resulting sodium cresolate solution is set free by neutralization; for this purpose the hydrochloric acid formed during chlorination can also be used. The coproduct sodium chloride can be returned to the chlor-alkali electrolysis.

For economic reasons, it is important that the starting materials are produced at locations sufficiently close to one another that conveyance through pipelines is possible. The technology of the process largely corresponds to that of the Dow – Bayer chlorobenzene – phenol hydrolysis process [76]. In the manufacture of cresols, however, the amounts of the byproducts formed

are larger than in this process: these include ditolyl ethers [bis(methylphenyl) ethers], in particular, tolylcresols [methyl(methylphenyl)phenols], and small amounts of toluene, phenol, benzoic acid, and off-gas from cracking (methane and hydrogen). The removal of small amounts of phenol by azeotropic distillation, e.g., with chlorotoluene, is dealt with in [77].

Whereas it is hardly possible to control the scale on which tolylcresol is formed, the formation of ditolyl ether can be controlled via the temperature, the residence time, and the sodium hydroxide concentration; in addition, the scale on which this byproduct is formed can be minimized by recycling. This possibility arises from the fact that ditolyl ethers are hydrolyzable, albeit less easily than the homologous diphenyl ether. Therefore, if the reaction is optimally controlled, yields of ca. 80 %, based on chlorotoluene, are attainable. However, ditolyl ether has several uses, e.g., as a heat transfer medium (Diphyl DT), as an electrical insulant (Baylectrol 4800; replacement for polychlorinated biphenyl), and as a precursor for tanning agents. Therefore, ditolyl ether is no longer recycled; indeed, the conditions may be adjusted to increase the selectivity for this compound.

The process gives very pure cresols, i.e., products that are almost free from other compounds. With a 1 : 1 *o*/*p*-chlorotoluene mixture, the *o*-, *m*-, and *p*-cresol isomers are present in a ratio of ca. 1 : 2 : 1. This ratio differs from that of the chlorotoluene input because isomerization via aryne intermediates is assumed to occur [78], [79] under the severe conditions of hydrolysis. After the *o*-cresol has been distilled, a *m*-/*p*-cresol mixture containing ca. 70 % *m*-cresol is obtained.

The plant can also be operated on pure *o*- or *p*-chlorotoluene. The hydrolysis of *p*-chlorotoluene then gives a 1 : 1 *m*-/*p*-cresol mixture, and hydrolysis of *o*-chlorotoluene gives a 1 : 1 *o*-/*m*-cresol mixture. Technically pure *m*-cresol is obtainable from the latter by distilling off the *o*-cresol.

Hydrolysis of chlorotoluene without substantial isomerization is possible under milder conditions (200 – 350 °C) with alkali metal hydroxide [79], [80], alkali metal carbonates [81], or ammonium hydroxide [82], or with alkali metal acetate or alkali metal propionate solution [83] in the presence of copper or copper compounds. These processes are not used industrially, among other things because the space – time yield decreases drastically at lower temperatures. Still the best results (nearly 100 % *p*-chlortoluene conversion in 3 – 6 h) are obtained at 250 – 280 °C with alkali metal hydroxide in the presence of copper and/or a copper compound and an additional oxidizing agent like air (O_2) or hydrogen peroxide [84].

1.4.3. Cymene Hydroperoxide Cleavage

The synthesis via cymene hydroperoxide, which is also known as the cymene – cresol process, permits the production of *m*- or *p*-cresol from the corresponding cymenes (isopropyltoluenes). It is unsuitable for the production of *o*-cresol. The process consists of three reaction steps:

1) Toluene propylation and cymene isomerization

2) Oxidation of cymene to cymene hydroperoxide

3) Peroxide cleavage

By comparison with the analogous Hock cumene process (→ Acetone), the cymene – cresol process has a lower space – time yield, involves considerably more costly distillation procedures, necessitates more extensive treatment of wastewater, and gives a product yield that is 20 – 30 % lower. The reasons for this are as follows:

1) All three isomers, *o*-, *m*-, and *p*-cymene, are formed in the propylation of toluene. Of the three isomers, *o*-cymene not only is hardly oxidized but also increasingly inhibits oxidation of the other cymenes [85] as its concentration in the isomer mixture rises. For continuous oxidation, the *o*-cymene content of the cymene mixture must be kept below 10 % at all times [86], [87]. Thus, cymene mixtures are needed that contain as little *o*-cymene as possible.
   The lowest *o*-cymene content is that of a cymene mixture in thermodynamic equilibrium [87], [88]. Aluminum chloride must be used to reach this equilibrium as quickly as possible [89–91]. The isomer ratio obtainable with aluminum chloride under practical conditions is ca. 3 % *o*-, 64 % *m*-, and 33 % *p*-cymene. As the *o*-cymene concentration rises while the oxidation is in progress, a large amount of the cymene must be returned to the first stage of the process after the cymene hydroperoxide and other byproducts have been separated, so that the *o*-cymene content can again be lowered to ca. 3 % by isomerization on aluminum chloride. The diisopropyltoluenes formed as byproducts in the alkylation and separated by distillation are also returned to this isomerization step.
2) The oxidation rates of the cymenes are lower than that of cumene. In addition, the cymenes can be oxidized up to a peroxide content of only ca. 20 %, whereas oxidation levels exceeding 30 % are possible with cumene. The proportion of unreacted cymene that must be distilled and returned to the reaction is therefore greater than in the cumene – phenol process. At higher degrees of oxidation, the formation of byproducts from excessive oxidation of the isopropyl group to dimethyl(tolyl)methanol and methylacetophenone is greatly increased.
3) The methyl group of the cymenes is likewise oxidized; for details of the mechanism of *p*-cymene oxidation, see [92]. The ratio at which the methyl group and isopropyl group are subjected to oxidative attack may be as high as 1 : 4 [93]. As the primary peroxide is less stable than the tertiary peroxide, it is more easily converted into secondary products (isopropylbenzyl alcohol, isopropylbenzaldehyde, cuminic acid). A more important drawback is that in the highly exothermic acid cleavage, in addition to isopropylphenol, 1 mol of formaldehyde is formed per mole of primary peroxide still present; because formaldehyde is able to bind up to 2 mol of cresol as a formaldehyde resin, the cresol yield is substantially diminished. Moreover, the presence of resin makes the product more difficult to work up. Various solutions to the problem have been proposed: (1) selective decomposition of the primary peroxide during the actual oxidation by adding catalytic amounts of picoline, pyrrole, thiophene [94], or triphenylphosphine [95]; (2) selective hydrogenation of the primary peroxide over a noble-metal catalyst [96], [97] after the oxidation in a separate stage of the process (before the acid cleavage) or decomposition by passing the primary peroxide over a magnesium aluminate catalyst [98] or treatment with sodium hydroxide and heavy metals [99] or organic quaternary ammonium salts [100]; (3) extraction of the primary peroxide [101–104]. However, it is simpler to dissolve the products resulting from methyl group oxidation continuously and as fully as possible in excess alkali solution present during the actual oxidation itself [85], [86], [105]. The organic acids present in the spent caustics (ca. 0.5 kg of cuminic acid, toluic acid, phthalic acid, and other products per kilogram of cresol) are largely precipitated during the acidification and can be removed by filtration. Addi-

tional removal from the filtrate (wastewater) is possible by extraction [106].
According to another suggestion, hydrogen peroxide should be present during cleavage of cymene hydroperoxide to cresol [107]; alternatively, this cleavage could be effected under mildly hydrogenating conditions [108]. These measures decrease the extent of yield-lowering side reactions undergone either by the primary peroxide or by its secondary product, formaldehyde.

4) The reaction mixture after acidic peroxide cleavage contains not only cresol, acetone, and unreacted cymene, but also isopropenyltoluene, 2-tolylpropanol, isopropylbenzyl alcohol, isopropylbenzaldehyde, methylacetophenone, isopropylphenol, and numerous other compounds. The separation of these byproducts is relatively expensive because of their large number, their similar boiling points, and the formation of azeotropic mixtures [109]. The amount of byproducts can be decreased if first the primary peroxide is selectively hydrogenated over a Pd/C or Pd/titania catalyst (see above) and then the reaction mixture, after concentration by distillation and acidic peroxide cleavage, is again hydrogenated over the same catalyst type under somewhat harsher conditions. The thereby re-formed cymene increases the yield of cresol (based on the cymene consumed) to 80 – 85 % [97].

Cymene – cresol plants, in which cymene mixtures are used and which have a nameplate capacity of 22 000 t/a each, have been operated in Japan by Sumitomo [110] and Mitsui since 1969. The product has a *m*- and *p*-cresol content of more than 99.5 % and a *m/p* ratio of 60 : 40. The acetone coproduct is of high quality [111].

If pure *p*- or *m*-cymene is used, the high cost of recycling and isomerization necessitated by the presence of *o*-cymene is eliminated, and pure *p*- or *m*-cresol can be obtained directly. For example, until 1972 the Hercules Powder Co. operated a plant at Gibbstown in the United States for the manufacture of *p*-cresol from *p*-cymene obtained from natural terpenes [112].

Owing to the close proximity of the boiling points of the cymene isomers (*m*-cymene 175.1 °C, *p*-cymene 177.1 °C, *o*-cymene 178.3 °C, at 101.3 kPa), the *m*-cymene, at most, may possibly be isolated at reasonable cost from the cymene mixture resulting from the propylation of toluene (see above) [91]. However, both pure *m*-cymene and pure *p*-cymene can be isolated according to UOP's Cymex process on *p*-cymene-selective 13X molecular sieves by using toluene as desorption agent [113]. The process corresponds to UOP's Parex process for the isolation of *p*-xylene from C_8 aromatics (→ Xylenes). A cymene – cresol plant, based on the UOP and Hercules Powder technologies, for the manufacture of pure *m*-cresol and *p*-cresol [for the antioxidant 2,6-di-*tert*-butyl-4-methylphenol (BHT)] was started up in 1986 at the Beijing Yanshan Petrochemical Corp. in China (nameplate capacity ca. 20 000 t/a). But it seems the facility is now also used for the production of phenol by the cumene process [114].

If in the Cymex process only one isomer, e.g., *p*-cymene, is required, the *m*-/*o*-cymene mixture leaving the adsorption column, which is impoverished with regard to *p*-cymene, can be reisomerized and returned to the separator [115]. Since it is less important in this case to have the lowest possible *o*-cymene content, the isomerization (and the alkylation) can, for example, be carried out on phosphoric acid – aluminum oxide catalysts at 370 °C instead of using aluminum chloride [115].

In the manufacture of *m*-cresol, *m*-cymene can also be obtained by selective cracking of the *p*-cymene present in cymene mixtures with a low *ortho* isomer content. Cleavage of *p*-cymene (and to a lesser extent that of *o*-cymene) to toluene and propylene is accomplished at 300 – 400 °C on shape-selective ZSM-5 zeolites [116] that are particularly selective in the MgO-modified Li^+-ZSM-5 form [117]. A further, technically less attractive way of isolating *m*-cymene consists of complexing with anhydrous hydrofluoric acid – boron trifluoride at temperatures below − 40 °C [118].

1.4.4. Methylation of Phenol

Synthetic cresol, especially *o*-cresol, and xylenol are now produced largely by methylation of phenol with methanol in the presence

of catalysts. 2,6-Xylenol is produced almost entirely by this method.

The process consists of only one reaction step, but is based on phenol, which is relatively expensive; the separation of products from the reaction mixture is also costly. This is partly because the boiling points of several components are very near one another, and partly because in some cases the purity of the product must meet very strict requirements.

The reaction can be carried out either in the vapor phase or in the liquid phase.

Methylation in the Vapor Phase. Vapor-phase methylation is used mainly to manufacture pure *o*-cresol and/or pure 2,6-xylenol:

Side reactions:

$$CH_3OH \longrightarrow CO + 2\,H_2O \quad \Delta H^0_{298} = -91\ \text{kJ/mol}$$

$$CO + H_2O \longrightarrow CO_2 + H_2 \quad \Delta H^0_{298} = -41\ \text{kJ/mol}$$

$$CO + 3\,H_2 \longrightarrow CH_4 + H_2O \quad \Delta H^0_{298} = -206\ \text{kJ/mol}$$

At atmospheric or slightly elevated pressure, a superheated mixture of the vapors of phenol, methanol, and water is passed at a liquid hourly space velocity (LHSV) of $1-2\ h^{-1}$ over a metal oxide catalyst fixed in a multitubular reactor of stainless steel at a temperature of 300 – 460 °C [119–121]. The reaction temperature required depends on the nature of the catalyst and on the desired composition of the product. The temperature is permitted to deviate from this level by only a few degrees.

The heat of the reaction is dissipated by boiling organic heat-transfer media [122], by circulating salt melts [120], or through the generation of high-pressure steam [121]. The slight loss of catalytic activity that occurs in the course of time is compensated by raising the temperature accordingly. Carbon deposits are removed from time to time by burning. The presence of water in the feedstock mixture suppresses the decomposition of methanol, extends the regeneration cycle, and prolongs the lifetime of the catalyst [123], [124], which may then endure for several thousand hours.

The product mixture leaving the reactor gives up some of its heat to the feedstock mixture in a heat exchanger, and is then condensed. The uncondensable reaction products formed from the decomposition of methanol (H_2, CH_4, CO_2, and CO) are used as fuel gas in steam production. Aqueous methanol is first distilled from the liquid reaction product and then recycled. Separation into methanol, water containing phenol, and the phenols can be achieved in a single distillation column with sidestream [125]. It is also possible to decant an aqueous methanol phase and to recycle it after adsorbing the contained phenols with an resin adsorbent (desorbing can be achieved with methanol) [126]. Water remaining in the product is then removed either by azeotropic distillation with toluene [122] or as an azeotropic mixture with unconverted phenol [121]. In the latter case, it is necessary to strip the phenol from the wastewater. The dehydrated mixture is then fractionated into phenol ether, phenol, *o*-cresol (≥ 99.5 %), and 2,6-xylenol in an additional series of highly efficient distillation columns operated continuously under vacuum. The phenol ether – phenol fraction is recycled. The distillation residue, which contains, among other compounds, 2,3-, 2,4-, and 2,5-xylenol and 2,4,6- and 2,3,6-trimethylphenol, is usually burned as a fuel oil. If the catalyst has high ortho selectivity, pure (99.5 %) 2,6-xylenol can be obtained directly. If that is not the case or if the reaction conditions are too severe (high temperature, long residence time), the 2,6-xylenol fraction will contain *m*- and *p*-cresol, which must be removed by special methods (Section 2.3). The ratio of *o*-cresol to 2,6-xylenol can be controlled by altering the methanol – phenol ratio, and if the *o*-cresol is recycled, 2,6-xylenol comprises the sole product. Over an extended production time, the yield (selectivity) of *o*-cresol and 2,6-xylenol, calculated on the basis of reacted phenol, is 90 – 98 %.

With regard to the use of a fluidized-bed reactor process and a high-performance silica-supported Fe – V oxide catalyst developed by

Asahi Chem. Ind. for the concurrent production of *o*-cresol and 2,6-xylenol at 320 – 340 °C (e.g., 84 % phenol conversion and 98 % selectivity at 336 °C), see [127], [128–132]. For kinetic data on a promoted Mn oxide catalyst and the use of adiabatic reactors for phenol methylation, see [133]. Vapor – liquid equilibrium data for the alkylation product are given in [134], and details of the distillation in [135–137]. An evaluation of the vapor-phase methylation of phenol to cresols and xylenols over a solid acidic catalyst is reported in [138].

Magnesium oxide catalysts, in particular, are used. They require relatively high operating temperatures (420 – 460 °C), but are so *ortho*-selective that *m*- and *p*-cresol are hardly formed, even at 540 °C [139]. The activity (phenol conversion), as well as the ratio of 2,6-xylenol to *o*-cresol and the *ortho* selectivity depend on the conditions under which the magnesium oxide is produced [140–142], [143]. These properties can be further improved by combining magnesium oxide with other oxides, such as those of the alkali metals [144], manganese [141], [145–147], copper [141], [142], [145], [148], titanium, uranium, zirconium, chromium [149], cerium [150], and silicon [151]. At 440 °C and at a liquid hourly space velocity (LHSV) of 2.0 h^{-1} the continuous reaction of a mixture of phenol, methanol, and water in a 1 : 4 : 2.4 molar ratio over an MgO catalyst thus gives a phenol conversion of ca. 82 %, and a molar ratio of 2,6-xylenol, *o*-cresol, *p*-cresol, 2,4-xylenol, and 2,4,6-trimethylphenol of 69.5 : 23.0 : 0.05 : 0.8 : 6.6. If the catalyst also contains ca. 1 % of copper, the conversion rate is 89 %, and the corresponding molar ratio of the products is 73.3 : 18.9 : 0.06 : 0.07 : 7.0. The waste gas volume is in both cases 0.5 mol per mole of reacted phenol [142]. The mechanism of *ortho* methylation is discussed in [152].

With *manganese oxide* catalysts [153] or *chromium oxide* catalysts [154–156] the methylation can be carried out at ca. 390 °C; and on catalysts based on *vanadium oxide* [157], [158] or *iron oxide* [159–164], [153, 165–168] at ca. 350 – 320 °C, provided that these oxides are combined with smaller amounts of other oxides (e.g., those of Ce, Cr, Mn, Co, Ni, Zn, Al, Ga, In, Si, Ge, Sn, Pb, Bi, Mg, Na) or with one other [127], [130], [131], [169–172]. By addition of, e.g., MgO [168] or Ce – Cr oxide [173] and doping with K_2O, the phenol conversion of the silica-supported V – Fe oxide fluidized-bed catalysts [130], [131] can be enhanced by 10 – 15 % to 93 – 99 % at 320 °C. These mixed oxide catalysts show excellent *ortho* selectivity and give a very high 2,6-xylenol/*o*-cresol ratio and virtually no *p*-cresol. At phenol/methanol molar ratios of ca. 1 : 3 – 6 and liquid hourly space velocities (LHSV) of ca. 1 h^{-1} they permit almost complete conversion of phenol, with 2,6-xylenol yields of up to ca. 97 % (calculated on the basis of phenol). Combination with other metal oxides also extends the catalyst lifetime (especially if alkali metal compounds are added) and diminishes the extensive decomposition of methanol typically seen with manganese, chromium, vanadium, and iron oxide catalysts. In spite of this measure and the addition of water vapor (generally 1 – 2 mol per mole of phenol), 1 – 2 mol of methanol is usually lost by decomposition for every mole of 2,6-xylenol manufactured. The proposed methods for reducing the loss include the addition of sulfur dioxide, hydrogen sulfide, nitric oxide, carbon monoxide, or carbon dioxide to the feedstock mixture [174], recycling a portion of the cracking gas [175], and introducing the methanol [176] or phenol at different parts of the reactor [177]. Relatively little methanol is decomposed on Fe_2O_3 catalysts doped with silicon oxide and magnesium oxide [162]. For the mechanism of the reaction on mixed oxide contacts, see [178], [179].

γ-Aluminum oxide catalyzes the methylation of phenol at a temperature as low as 300 – 320 °C. Under these conditions, at a methanol : phenol molar ratio of 1 : 2, and at a liquid hourly space velocity (LHSV) of 1 h^{-1}, *o*-cresol, 2,6-xylenol, and *m-/p*-cresol mixture are formed in a molar ratio of ca. 82 : 17 : 1, with a total selectivity of 97 % and a phenol conversion of 33 % [180]. Increasing the methanol : phenol ratio and recycling the *o*-cresol enables the *o*-cresol : 2,6-xylenol ratio to be shifted toward 2,6-xylenol [181].

On γ-Al_2O_3, unlike other methylation catalysts, methanol is scarcely decomposed under the conditions described above. In addition, this catalyst must be regenerated only once in ca. 1000 h, and has a working lifetime of several years [182]. Its disadvantage is that to prevent the formation of significant quantities of other di-, tri-, and tetramethylphenols, the phenol con-

version rate must not substantially exceed 60 %, which means that relatively large amounts of the product must be worked up and recycled. In addition, extensive operations, e.g., extractive distillation with diethylene glycol [181], are necessary to free the 2,6-xylenol from the *p*-cresol that is unavoidably formed on this catalyst.

Below 300 °C, increasing amounts of anisole are formed on γ-Al_2O_3; however, because anisole is isomerized to cresol at elevated temperatures [183], [184], only a small amount ($\leq$ 2.5 %) is present in the reaction mixture under the previously mentioned conditions. As the temperature and residence time are increased, the rate of phenol conversion on Al_2O_3 rises, but the *ortho* selectivity falls. This is also basically true of other catalysts. Instead of *o*-cresol and 2,6-xylenol, increasingly large amounts of *m*- and *p*-cresol, other xylenols, multimethylphenols, and methylbenzenes, especially hexamethylbenzene, are formed [185], [186]. Demethylation occurs above 500 °C [187]. Increasing the temperature also results in the formation of larger amounts of gaseous cracking products, and accelerates the carbonization of the catalyst, thus necessitating more frequent regeneration.

The reaction kinetics and the choice and calculation of an optimum multitubular reactor for phenol methylation on γ-Al_2O_3 are discussed in [188–190]. Industrial plants are described in [119] and [181].

Aluminum oxides with strong acid sites [191], *silica – alumina* [152], [192], *zeolites* [192–198] *aluminum phosphates* [186], [199], and *phosphoric acid – kieselguhr* [199] have enhanced isomerization and transmethylation properties. Therefore, they lead to products with a relatively high *m/p* content, especially if the temperature is simultaneously raised to ca. 450 °C. In addition, at a temperature of 250 – 300 °C, shape-selective zeolites [193–195], [200], [201], e.g., of the HKY type [193], and also phosphoric acid – kieselguhr [199], show remarkably high selectivity for *p*-cresol, giving a *m*-/*p*-cresol mixture with *p*-cresol contents of ca. 85 % [193] or 77 % [199], respectively. *Pentasil zeolites* modified, e.g., with Mn [202], Mg, or P [203], also show *para* selectivity.

As alternatives to methanol, methylbenzenes [205–207], dimethyl ether [208], methylamine [209], methane [210], carbon monoxide – hydrogen mixtures [211], and formaldehyde – hydrogen mixtures [212] have been proposed as methylating agents.

Methylation in the vapor phase is utilized by General Electric Co. in the United States (capacity ca. 5000 t/a *o*-cresol and ca. 70 000 t/a 2,6-xylenol) and in the Netherlands (ca. 20 000 t/a 2,6-xylenol); by Inspec Fine Chemicals (formerly Synthetic Chemicals, now a part of Laporte) in the United Kingdom (capacity ca. 10 000 t/a *o*-cresol and 2,6-xylenol, but the plant is also used for the production of 2,4-xylenol by methylation of *p*-cresol and for 2,5-xylenol and 2,3,6-trimethyphenol by methylation of *m*-cresol); Chemopetrol in the Czech Republic (capacity ca. 10 000 t/a *o*-cresol, *m/p*-cresol, 2,6-xylenol and other xylenols); and in Japan by Nippon Crenol (joint venture of Asahi Chemical Industry and Nippon Steel Chemical Company; capacity ca. 8000 t/a *o*-cresol and 15 000 t/a 2,6-xylenol), GEM Polymers (joint venture of General Electric Company, Mitsui Chemicals Co., and Mitsui Toatsu Chemicals; capacity ca. 2500 t/a *o*-cresol and ca. 11 500 t/a 2,6-xylenol), Mitsubishi Gas Chemical Company (capacity ca. 5000 t/a 2,6-xylenol) and Honshu Chemical Industry Co. (capacity ca. 5000 t/a 2,5-xylenol and mainly 2,3,6-trimehyphenol by methylation of *m*-cresol). A vapor-phase methylation plant is said to be in operation in Russia, and activities are also reported from China [213].

Methylation in the Liquid Phase. Results similar to those achieved in the vapor phase are obtained if the oxide catalysts (particularly γ-Al_2O_3) are suspended in a phenol – methanol mixture and heated in an autoclave to 300 – 400 °C [214–216]. The mixture of phenol and methanol [217] or of *o*-cresol and methanol [218] can also be passed as a liquid over a γ-Al_2O_3 catalyst forming a fixed bed in a tube reactor. At 350 °C and a phenol : methanol molar ratio of 0.7 : 1, the pressure is ca. 35 bar [217].

According to a process developed by Chemisches Werk Lowi (now Great Lakes Chemical Corporation) in Germany, phenol and an equimolar amount of methanol are reacted in an autoclave at 350 – 400 °C in the presence of 2 – 3 wt % *aluminum methylate,* with the water of the reaction, together with some of the methanol, being distilled through a small column.

After the catalyst residue has been removed by filtration, the product is worked up by distillation. Methanol, anisole, and phenol are recycled. The yield of cresols and xylenols is ca. 80 % [219], calculated on the basis of converted phenol (ca. 60 %). The main product is *o*-cresol; *m*- and *p*-cresol, 2,6-, 2,4-, and 2,3-xylenol, and trimethylphenols are also formed. The ratio of the products can be adjusted by altering the phenol : methanol ratio, the temperature, and the residence time. The presence of bases (e.g., pyridine) increases the conversion [220], whereas that of acids raises the proportion of *p*-cresol and 2,4-xylenol in the product [221]. Aluminum phenolate can also be used as a catalyst [222]. If necessary, the process can be operated in a multipurpose plant, the capacity of which may be ca. 2000 – 3000 t/a.

Until 1990 Union Rheinische Kraftstoff AG (meanwhile DEA-Mineraloel AG, Werk UK-Wesseling) in Germany operated a process (also known as the Biller process) that used *liquid-phase catalysts* [223], [224], preferably aqueous zinc halide – hydrogen halide solutions [225], at 200 – 240 °C and pressures of ca. 25 bar (2.5 MPa). After the reaction, the organic components were separated from the aqueous catalyst phase by extraction with benzene or cyclohexane, washed with water several times, and worked up by distillation. The catalyst solution was united with the washing water, concentrated, and recycled [226]. The main products were *o*-cresol, *p*-cresol, 2,4-xylenol, and 2,6-xylenol. At a phenol : methanol molar ratio of 1 : 0.6, yields of up to 98 % were obtainable, calculated on the basis of converted phenol. Compared with other processes, this had the advantages not only that *p*-cresol and 2,4-xylenol are obtained in considerably larger quantities, but also that, provided the reaction conditions were carefully harmonized, the *p*-cresol was almost free of *m*-cresol. The extent of *para* substitution increased with the methanol content of the feedstock mixture, but the yield fell. The process required materials that were highly resistant to corrosion, e.g., a reactor lined with tantalum. The plant capacity was ca. 16 000 t/a. The product ratio was controllable within certain limits. As an example, a possible *o*-cresol, *p*-cresol, 2,4-xylenol, and 2,6-xylenol ratio was 7 : 5 : 2 : 1.

Transmethylation and Isomerization. After phenol has been added to the methylphenol residues either from the methylation of phenol or of different origin, or to xylenol for which there is no other use, reaction can occur in the presence of alkylation catalysts to give a product consisting mainly of *o*-cresol, together with *m*-/*p*-cresol. The reaction may proceed either in the vapor phase or in the liquid phase; the temperature is 400 – 500 °C. Catalysts are aluminum oxide [227], chromium oxide – aluminum oxide [228], silica – alumina [229–231], metal oxide – iron oxide [232], or magnesium oxide – tungsten oxide [233]. In the case of 2,6-xylenol, this transmethylation, accompanied by isomerization, can also be accomplished without a catalyst in the vapor phase at 550 – 600 °C or, batchwise, in the liquid phase at 420 – 470 °C [234]. In this way, the *o*-cresol yield from the methylation of phenol can be raised. For cresol isomer mixtures the Chiyoda Chemical Engineering Construction Co. has developed an isomerization – transalkylation process with phenol on silica – alumina catalysts at 400 °C at normal pressure (LHSV 0.5 h^{-1}) which allows the isolation of pure *o*-cresol by recitification of the resulting mixture and recycling of all the other phenolic components [230]. The isolation of pure *m*-cresol (or *p*-cresol) is possible in the same way if the *m*/p rectification cut is additionally passed through a Y zeolite adsorption unit and the unwanted isomer is recycled with the other phenols [231].

Owing to the temporary lack of demand for *o*-cresol, opportunities for isomerizing it to *m*- and *p*-cresol have been investigated. The results formerly obtained with aluminum chloride [235], [236], aluminum fluoride, boron trifluoride, aluminum silicates, or aluminum oxide were unsatisfactory [236], [237] because resinification and disproportionation to phenol, dimethylphenols, etc. occurred in addition to isomerization.

Isomerization without substantial disproportionation is possible, however, on silica – alumina zeolites of the ZSM group [238–240]; at a temperature of ca. 400 °C and *o*-cresol conversions of 40 – 50 %, *m*-/*p*-cresol selectivities of 90 % and an *m* : *p* ratio of 7 : 3 are possible [238].

1.4.5. Other Routes

The rising demand for cresol has stimulated the development of numerous syntheses, especially those that lead selectively to certain cresol isomers. It appears, however, that these processes are not yet being used industrially.

Gulf Oxychlorination. A cresol synthesis analogous to the Raschig phenol synthesis cannot be carried out satisfactorily under industrial conditions: at the temperature needed for oxychlorination in the vapor phase (Eq. 5), toluene is oxidized to a considerably greater extent than benzene, and only low rates of toluene conversion are therefore possible.

$$CH_3-C_6H_5+HCl+0.5\,O_2 \longrightarrow CH_3-C_6H_4-Cl+H_2O \quad (5)$$

$$CH_3-C_6H_4-Cl+H_2O \longrightarrow CH_3-C_6H_4-OH+HCl \quad (6)$$

In a process developed by the Gulf Research Development Co., these disadvantages are avoided by oxychlorinating the toluene with aqueous hydrochloric acid and oxygen at a temperature of ca. 100 °C in the presence of catalytic amounts of nitric acid and a palladium or copper salt [241], [242]. At toluene conversion rates of 80 %, primarily *o*- and *p*-chlorotoluene are obtained in a 2 : 1 molar ratio and with a selectivity of $\geq$ 95 %.

The subsequent hydrolysis of the chlorotoluene mixture is carried out in the vapor phase at 400 – 450 °C, as in the Raschig process, but over improved catalysts, such as lanthanum phosphate that may be activated with copper [243]. At a chlorotoluene conversion of 20 %, the cresol selectivity is ca. 95 %. The isomer ratio differs from that given by the processes already being used industrially. A large amount of *o*-cresol is obtained in addition to *p*-cresol containing some *m*-cresol.

If the hydrochloric acid liberated in the hydrolysis step (Eq. 6) is returned to the oxychlorination reactor, the process becomes equivalent to the oxidation of toluene with oxygen. This fact, together with the high conversion rates and selectivities, makes the process interesting. Commercial exploitation of the process necessitates the extensive recycling and places severe demands on the resistance of the plant to corrosion.

The Gulf oxychlorination process is equally applicable to xylenes, and is therefore also suitable for the manufacture of xylenols.

Oxidative Decarboxylation of Methylbenzoic Acids. As in the Dow process for the manufacture of phenol from benzoic acid, methylbenzoic acids are decarboxylated to cresol when an air – steam mixture is passed through their melt at 200 – 240 °C in the presence of copper and magnesium salts [244].

By comparison with the manufacture of phenol, the cresol process is more complex and 10 – 15 % less selective [60]. This is due partly to the fact that cresols have higher boiling points; in consequence, optimal control of the reaction is difficult, and a greater amount of tar is formed [244]. For a means of reducing the tar formation, see [245]. In addition, the simultaneous successive oxidation of the methyl group leads to numerous byproducts [246]. Oxidation in the presence of benzoic acid has been proposed [247] as a mean of preventing the sublimation of methylbenzoic acid.

Better results are achieved when a methylbenzoic acid – steam mixture is oxidized in the vapor phase with oxygen – nitrogen mixtures over mixed catalysts at a temperature of ca. 300 °C [248], [249]. Thus, the reaction of a mixture of *p*-methylbenzoic acid, water, oxygen, and nitrogen (molar ratio of 1 : 18 : 1 : 9) at 300 °C over a Mo – V – Cu – Zn – Na oxide catalyst supported on γ-Al_2O_3 is reported to give a *m*-cresol selectivity of 90 % at a methylbenzoic acid conversion rate of 80 %; as byproducts, 2 % toluene, 5 % bis-(methylphenyl) – bis(methylphenyl) ether mixture, and 3 % of additional carbon dioxide are formed [249].

The process could be of interest in the manufacture of pure *m*-cresol, since only *m*-cresol is formed from both the *ortho* and the *para* forms of methylbenzoic acid [60], [244]. *m*-Methylbenzoic acid gives (in the liquid phase)

o- and *p*-cresol in a 1 : 2 ratio [250], [251]. Regarding the mechanism and kinetics, see [244], [246], and [252], respectively.

The required methylbenzoic acids can be obtained by oxidation of the corresponding xylenes, which are, however, more expensive than toluene.

Baeyer – Villiger Oxidation of *p*- or *o*-Methylbenzaldehyde. This route leads to *o*-cresol or, more interestingly from the practical aspect, specifically to *p*-cresol. Hydrogen peroxide reacts with excess formic acid to give performic acid (Eq. 7), which oxidizes *p*-methylbenzaldehyde to *p*-tolyl formate (Eq. 8); hydrolysis (Eq. 9) then leads to *p*-cresol and formic acid.

(7)

(8)

(9)

Several variants of the process have been developed [253–255]. The most favorable process was probably invented by Mitsubishi [256]. Hydrogen peroxide (1.2 mol; 90 %) is added to a mixture consisting of 1 mol of *p*-methylbenzaldehyde, 14 mol of formic acid, and ca. 10 % (4.5 mol) of water. The temperature of the mixture is maintained at 60 – 90 °C; the heat of the reaction is removed by reflux condensation under vacuum. Because of the presence of water, formate is hydrolyzed; after a reaction time of 1 h, the *p*-methylbenzaldehyde conversion rate is 100 % and the *p*-cresol yield is 85 %. If, instead of 90 % hydrogen peroxide, performic acid is used, or if the process is carried out in the presence of a solid acid (zeolite or ion-exchange resin), the yield rises to 90 – 92 %. The product is worked up by distilling the formic acid. Apart from the additional amount formed in the process, the formic acid, which has a concentration of ca. 90 %, is recycled. The *p*-cresol is then isolated from the residue, which still contains 10 – 20 % of high-boiling constituents [256].

The starting material, *p*-methylbenzaldehyde, can be produced from toluene and carbon monoxide by the so-called MGC PTAL process developed by Mitsubishi [257]. It is an intermediate in the manufacture of terephthalic acid.

Nucleus Hydroxylation. The direct hydroxylation of toluene (or xylene), e.g., with oxygen [258–260], in a plasma [261–263], in fuel cells [264], or in the presence of hydrogen [265], with hydrogen peroxide [266–269], inorganic peroxo compounds [270], [271], organic peroxides [272], [273], or iodosyl acetate [274], in the presence of various catalyst systems (Friedel – Crafts catalysts, transition-metal compounds, or irradiation), has been extensively investigated. In contrast to this, hydroxylation of toluene with specific microorganisms gives regioselectively *p*-cresol [275–277].

According to Rhône-Poulenc, the most successful results so far have been obtained with 85 % hydrogen peroxide in the presence of a large amount of trifluoromethanesulfonic acid and a small amount of phosphoric acid (for complexing metal ions) [278].

2 : 1

At – 20 to – 15 °C and a molar ratio of H_2O_2, toluene, CF_3SO_3H, and H_3PO_4 of ca. 1 : 10 : 17 : 0.04, *o*- and *p*-cresol are obtained in a 2 : 1 ratio in 80 % yield (calculated on the basis of hydrogen peroxide) at a toluene conversion rate of 10.6 %. One of the prob-

lems is the recycling of the very expensive trifluoromethanesulfonic acid.

Work carried out by UOP indicates that relatively good results are obtainable with hydrogen fluoride, which is less expensive and easier to handle industrially than trifluoromethanesulfonic acid, in the presence of carbon dioxide. With 30 % hydrogen peroxide at 0 °C and at a molar ratio of H_2O_2, toluene, HF, and CO_2 of 1 : 10 : 70 : 10, *o*- and *p*-cresol are obtained in a 2 : 1 ratio in 67 % yield, based on hydrogen peroxide, in addition to a small amount of *m*-cresol. *m*-Xylene gives mainly 2,4-xylenol, *p*-xylene mainly 2,5-xylenol, and *o*-xylene mainly 2,3- and 3,4-xylenol [279]. The effect of the carbon dioxide is not fully understood, but this compound acts to some extent as an internal coolant.

On titanium-modified zeolites, *o*-, *m*-, and *p*-cresols in a 14 : 11 : 75 ratio are formed in a yield of at least 40 %, based on H_2O_2, when a mixture of H_2O_2, water, toluene, methyl isobutyl ketone, and titanium zeolite (pretreated with H_3PO_4) is heated under reflux in a mass ratio of 1 : 7 : 17 : 10 : 2.6 [280]. For results on HY zeolites and titanium silicalite, see [281] and [282].

Cresols can also be obtained by oxidation of toluene with N_2O in the presence of H-ZSM-5 zeolites containing Lewis acidic extra framework Fe, Al [283], or Ga [284]. Thus, toluene with N_2O (molar ratio 1 : 3) at 350 °C/ 1 bar/ WHSV 1 h^{-1} on a H-[Al]ZSM-5 zeolite was oxidized to cresol with 24 % conversion and a selectivity of ca. 27 % (molar ratio *o*- : *m*- : *p*-cresol = 52 : 32 : 16). Besides some higher molecular aromatics the product mixture consisted of benzene, xylene, and phenol [283].

ICI has developed a cyclic process equivalent to the oxidation of toluene with peracetic acid, which gives yields of up to 95 % of an *o*-/*p*-cresol mixture, free of the meta isomer, with a cresol content of 92 %. The "catalyst" in the reaction is iodotoluene. This is oxidized by peracetic acid to iodosyltoluene, which without isolation reacts with toluene and sulfuric acid to form ditolyliodonium hydrogen sulfate. Hydrolysis is effected by diluting the reaction mixture. Cresol is produced; iodotoluene is simultaneously regenerated and recycled [285].

Until now all processes involving nucleus hydroxylation have been unsatisfactory for several reasons; for example, the cresols must be isolated from very dilute solutions, and considerable amounts of auxiliaries and unreacted starting materials must be recycled with as little waste as possible.

Oxidative Methylation of Toluene. At the All-Russian Research Institute for Organic Synthesis Co., Moscow, a pilot plant has been operating in which toluene is oxidized adiabatically in a tube reactor at 700 – 750 °C and with contact time of 0.2 – 0.5 s with oxygen in the presence of methane and steam (molar ratio 1 : 1 – 2 : 10 – 20 : 2 – 6) [286], [287].

At a toluene conversion per pass of ca. 45 %, 0.52 t of ethylbenzene and styrene, 0.25 t of benzene, ca. 0.11 t of phenol, and ca. 0.06 t of cresol are obtained per tonne of toluene [288], [289]. Thus, if the process were to be used on the scale customary for petrochemical operations, it should be possible to produce considerable amounts of cresol by the "direct oxidation" of toluene.

Hock Reaction of Toluene Derivatives. As in the cymene – cresol process, other toluene hydrocarbons can be peroxidized and cleaved to give cresol and the corresponding carbonyl compound. Particular interest has been shown in toluene derivatives that give *p*-cresol and are more readily accessible than *p*-cymene, e.g., ethylidenebis(*p*-methylbenzene) (coproduct: *p*-methylacetophenone) [290], [291], 4-methylcyclohexylbenzene (coproduct: cyclohexanone) [292], and *p*-xylene (coproduct: formaldehyde) [293], [294]. Oxidation of xylene in the presence of acetic acid gives the corresponding cresyl acetate, which can be hydrolyzed to form cresol [295].

Hydrogenation of *N,N′*-Dialkylaminomethylphenols. The reaction of phenol with paraformaldehyde and, e.g., piperidine in methanol at a 2 : 1 : 1 : 100 molar ratio at ca.

10 °C gives a mixture of piperidinomethylphenols, which without isolation is directly hydrogenated at 120 – 130 °C and 1 MPa over a palladium – carbon catalyst:

o-Cresol and *p*-cresol in a 1 : 2 molar ratio are obtained in a yield of ca. 90 %, based on converted phenol, or of about 75 %, based on the formaldehyde input. In addition, some 2,4-xylenol is formed (2 – 5 %) without *m*-cresol [296]. The yield is lower (65 – 70 %) if dimethylamine is substituted for piperidine.

Diels – Alder Ring Closure of Isoprene and Vinyl Acetate. The Diels – Alder route leads selectively to *p*-cresol in three reaction steps: (1) Isoprene (1 mol) reacts with vinyl acetate (20 mol) in the presence of 1 % hydroquinone in an autoclave at 180 °C; (2) the reaction product, 1-methylcyclohexen-4-yl acetate, is saponified; and (3) finally, the 1-methylcyclohexen-4-ol is dehydrogenated catalytically to *p*-cresol [297]:

High yields are claimed to be possible when the starting materials are recycled.

Carbonylation. 2-Methallyl chloride, acetylene, and carbon monoxide in acetone as solvent give *m*-cresol in 74 % yield at room temperature.

The catalyst consists of tetracarbonylnickel, sodium iodide, iron powder, and thiourea; magnesium oxide neutralizes the hydrochloric acid formed [298].

From Toluidines. Under severe conditions, toluidines in the presence of acidic catalysts (H_3PO_4, HCl, $ZnCl_2$, BF_4) can be hydrolyzed to form the corresponding cresols [299], [300]. Higher yields can be achieved by boiling the diazonium salts obtainable from toluidines [301–303]. Continuous operation of the process is described in [304].

Hydrodealkylation of Xylenols. Xylenols can be demethylated to phenol and cresols with hydrogen under pressure, either thermally at 600 – 700 °C [25] or on metal oxide catalysts at 400 – 500 °C [305]. Simultaneous deoxygenation enables BTX aromatics (BTX = benzene – toluene – xylene) to be produced at the same time. In this way, additional cresols can be produced, if necessary, from the xylenol fractions that are formed on a large scale in the gasification and hydrogenation of coal and other processes.

1.5. Separation of *m*- and *p*-Cresol [30]

Only *o*-cresol can be separated as a pure product by distillation from mixtures of the three cresol isomers. *m*-Cresol and *p*-cresol are obtained as a single fraction because the difference between their boiling points is too small for separation by distillation, even when carried out under vacuum.

1.5.1. Physicochemical Processes

Crystallization. According to the melting point diagram for *m*-/*p*-cresol mixtures (Fig. 1), it is possible to obtain, at normal pressure, pure *p*-cresol from mixtures containing more than

58 % *p*-cresol, and pure *m*-cresol from mixtures containing more than 89 % *m*-cresol. *Meta/para* mixtures containing 42 – 89 % of *m*-cresol cannot be separated by crystallization at normal pressure because *m*- and *p*-cresol exist as a molecular compound in a 2 : 1 molar ratio within this concentration range.

Figure 1. Liquid–solid phase diagram of *m*- and *p*-cresol mixtures under pressure [306]

The range within which *p*-cresol can be isolated by crystallization can be extended by applying pressure (Fig. 1); simultaneously the crystallization temperature and also the *p*-cresol yields, relative to crystallization at normal pressure, are raised [306], [307].

Crystallization is of practical importance as a technique for the separation of pure *p*-cresol from *m*-/*p*-cresol mixtures of high *p*-cresol content obtained from syntheses or other processes. Usually, this method has generally been carried out at normal pressure [308]. In Japan, a high-pressure crystallization technique known as the *Finecry process,* in which a liquid *m*-/*p*-cresol mixture is introduced into a high-pressure vessel of the piston cylinder type and crystallized adiabatically at 200 MPa, has been developed for industrial use by Kobe Steel. After the mother liquor has been drawn off and the plant decompressed, the *p*-cresol emerges as a pure crystalline product. The computer-controlled crystallization – decompression cycle lasts 2 – 5 min [309]. A plant for the separation of 500 t/a *p*-cresol with a purity of ≥ 99.5 % from its ≥ 70 % *p/m* mixtures has been operated since 1986 by the Sumitomo Chemical Co. in Japan [310].

Adsorption. Alkali metal-modified or alkaline earth metal-modified zeolites of type X, A [311], [312], L, or ZMS-5 [313], and also titanium dioxide [314], adsorb *p*-cresol more strongly than *m*-cresol. Thus, one can separate *m*-/*p*-cresol mixtures in an adsorption column and dissolve them again with a suitable desorbing liquid such as an aliphatic alcohol [311], e.g., a mixture of 1-hexanol and 2-heptanol [312], or a ketone [315]. A continuous version of this process has been developed by UOP [113]. It is known as the *Cresex process* and is used industrially in the United States by Merichem. The separating efficiency of the process not only depends on the adsorbent, but is also influenced to a large extent by the desorbent. With 1-hexanol, for example, only one isomer, either *m*- or *p*-cresol, can be isolated at a purity of ca. 99 % in a single operation (1 column); the purity of the other isomer obtained is only ca. 91 %. With 1-pentanol, however, a mixture containing ca. 69 % *m*-cresol and 31 % *p*-cresol can be separated into an extract containing 98.9 % of *p*-cresol and a raffinate containing 99.2 % of *m*-cresol in a single operation [113]. Phenolic impurities present in the cresol feed, e.g., *o*-cresol, *o*-ethylphenol, 2,4-, 2,5-, and 2,6-xylenol, migrate into the *m*-cresol during the adsorptive separation; hence, only pure *p*-cresol can be obtained in one operation if these impurities are present in significant quantities [113]. From mixtures containing additive neutral oils, *o*-cresol, ethylphenol and 2,6-xylenol, *p*- and *m*-cresol can be coextracted in an adsorptive pretreatment step [316].

Other Methods. The separation of *m*-/*p*-cresol mixtures by azeotropic rectification with benzyl alcohol [317] or by countercurrent extraction with selective solvents (aqueous methanol – gasoline) [318] has acquired no practical importance. This also applies to dissociative extraction and rectification processes that exploit the higher dissociation constant (higher acidity) of *m*-cresol in relation to that of *p*-cresol. Dissociative extraction uses systems consisting of aqueous sodium hydroxide solution [319], [320], aqueous trisodium phosphate solution [321], or aqueous aminoethanol solution [319] and an organic solvent, e.g., benzene, hexane, or toluene, by which the *p*-cresol is isolated in a multistep extraction. In dissociative rectifi-

cation, an amount of sodium hydroxide solution equivalent to the *m*-cresol content is added to the mixture and the *p*-cresol is distilled through a column with a large amount of water vapor as an azeotrope [322]. The separation of *m*/*p*-cresol can also be achieved by extractive rectification in the presence of diethanolamine or aniline as reactive entrainers [323].

1.5.2. Separation via Addition Compounds

m-Cresol and *p*-cresol form addition compounds with anhydrous calcium bromide; the compound formed with *p*-cresol has the higher thermodynamic stability. If an *m*-/*p*-cresol mixture in toluene is heated to 100 °C with 1 mol of calcium bromide per mole of *p*-cresol, the precipitate that is filtered off after ca. 8 h consists practically only of the adduct of *p*-cresol, while the *m*-cresol content of the mother liquor is correspondingly higher. If the *p*-cresol adduct is then decomposed, e.g., by heating to 200 °C, *p*-cresol with a purity of ca. 98 % is obtained, together with reusable calcium bromide [324]. Pure *m*-cresol can be isolated from the mother liquor rich in *m* isomer by selective adduct formation, e.g., with sodium acetate [325] or urea [326]. Pure *m*-cresol can also be obtained from the mother liquor after cooling to ca. 0 to − 5 °C and adding calcium bromide. Under these kinetically controlled conditions, the main product is the *m*-cresol – calcium bromide adduct, the subsequent decomposition of which gives *m*-cresol [327]. In adduct formation with excess calcium bromide at 25 – 30 °C, the *m*-cresol content of the mother liquor is directly rendered practically free of *p* isomer. The *p*-cresol from the adduct then contains correspondingly more *m*-cresol [328]. It is not known whether this process, which was developed by the Koppers Co. and has many variants, is being used industrially. Lithium bromide, magnesium bromide, or magnesium chloride can be used in place of calcium bromide, but the results are less satisfactory [324–328].

Many organic nitrogen compounds react with *m*- or *p*-cresol to form crystalline addition compounds that can be separated from the reaction mixture and decomposed to regenerate the nitrogen compound and the respective cresol isomer [30]. Benzidine was formerly considered particularly suitable for the separation of *m*- and *p*-cresol by virtue of the position of, and difference between, the melting points of its adducts; however, not only the carcinogenic properties of this compound but also other considerations now preclude its use. A more suitable and practical process is one in which benzylamine as the auxiliary substance forms with *m*-cresol a 1 : 1 adduct, which has a melting point of 39.5 °C. The adduct is centrifuged and fractionated in two distillation columns operating at different pressures (101.3 and 11.3 kPa) in such a manner that the benzylamine is recovered at the top of column 1 while pure *m*-cresol is obtained at the top of column 2. The mother liquor is distilled in the same way, then pure *p*-cresol is isolated by crystallization from the *m*-/*p*-cresol mixture rich in *p* isomer obtained in this case at the top of column 2. The benzylamine is recycled [329]. An auxilary substance for separation of *p*-cresol as an 1 : 1 addition compound from *m*/*p*-cresol mixtures by melt crystallization in the range of 0 – 50 °C is 2-pyrrolidinone, which thereafter is recovered from the *p*-cresol and the mother liquor by distillation and then recycled [330]. Strategies for the separation of *m*/*p*-cresol by adduct cristallization with ethylendiamine are discussed in [331].

The isolation of *m*-cresol via the 1 : 1 addition compound with urea is a process of some industrial importance. Formerly, the separated adduct was decomposed by heating with water. Now it is decomposed in the organic solvent in which the adduct has been formed. The procedure is as follows:

Urea (1.25 mol per mole of *m*-cresol) is added to a mixture of *m*-/*p*-cresol (65 : 35; 2 parts by weight) and toluene (0.5 parts by weight) at 30 °C. The mixture is cooled to − 10 °C, centrifuged, and washed with toluene (0.2 parts by weight). The product, consisting mainly of the urea adduct, is introduced into toluene (1.5 parts by weight), heated at 80 °C for 10 min, and filtered hot; almost all the urea is thereby held back. Distillation of the filtrate gives toluene, while that of the residue gives ≥ 98 % *m*-cresol in 89 % yield [332].

Advantage may be taken of adduct formation between cresols and certain other phenols with a view to effecting separation. For example, *m*-cresol forms with phenol an adduct with a melting point of 25.9 °C [333], while *p*-cresol forms an adduct with bisphenol A [isopropylidenedi(*p*-

phenol)] [334]. Furthermore, *m*-cresol gives with 1,4-dioxane at 20 °C and 110 – 130 MPa an addition compound that has been proposed for the separation of *m*-cresol from *m*-/*p*-cresol mixtures in which the content of *m*-cresol is high [335]. With α-cyclodextrin under aqueous conditions *p*-cresol preferentially precipitates as an inclusion complex (clathrate), from which *p*-cresol can be isolated in an enriched form by dissolution and extraction with water and ether [336].

m-Cresol can be precipitated as an addition compound with anhydrous sodium acetate from *m*-/*p*-cresol mixtures (e.g., in the ratio 65 : 35) in an organic solvent (gasoline, benzene, or toluene) at 20 – 40 °C. The precipitate is removed from the mother liquor and decomposed in the same solvent by heating to 80 – 95 °C; the sodium acetate is filtered. *m*-Cresol is obtained from the organic solvent as a technically pure product (96 – 99 %). The yield is ca. 70 % [30]. Higher yields (75 %) and improved *m*-cresol purity (99.5 %) are said to be possible if the adduct is decomposed at room temperature with polar solvents such as acetone [337].

1.5.3. Separation via Ester or Salt Formation

The mother liquor enriched with *p*-cresol (e.g., to a *m/p* ratio of 35 : 65) from the precipitation with sodium acetate can react with oxalic acid – with azeotropic dewatering – to give the semiester or diester, which is precipitated on cooling to 20 °C. The ester is separated and then hydrolyzed by heating with water at 85 % in the presence of the respective nonpolar solvent. The oxalic acid may be precipitated on cooling and recycled. The *p*-cresol dissolves in the organic solvent, from which it is isolated by distillation. The alternating use of both processes separates *m*- and *p*-cresol almost entirely [338].

Separation of the cresols via the calcium cresolates, in which advantage is taken either of the relatively greater solubility of the calcium *p*-cresolate or of the easier hydrolyzability of the *m*-cresolate with superheated steam, is unsatisfactory and has no practical importance.

1.5.4. Separation by Nuclear Substitution

Partial separation of cresols is possible by taking advantage either of the lower solubility of *p*-cresolsulfonic acid in sulfuric acid [30], of the more rapid formation of *m*-cresolsulfonic acid during sulfonation [339], or of the fact that the rate of hydrolysis of *m*-cresolsulfonic acid is faster than that of *p*-cresolsulfonic acid [340]. The last-mentioned difference forms the basis of the Bruckner process, the continuous operation of which in a reaction tower is described in [341].

A large-scale industrial process, e.g., used by Bayer in Germany and by Sumitomo and Honshu in Japan, comprises the separation of *m*- and *p*-cresol via the di-*tert*-butyl derivatives. In this technique, the *m*-/*p*-cresol mixture reacts with up to 2 mol of isobutene per mole of cresol in the presence of acidic catalysts (sulfuric acid). The resulting alkylated product consists mainly of 2,6-di-*tert*-butyl-*p*-cresol (*bp* 147 °C at 2.67 kPa) and 2,4-di-*tert*-butyl-*m*-cresol (*bp* 167 °C at 2.67 kPa), which are easily separated by distillation, provided that the catalyst has first been entirely inactivated. The process also yields monobutylated cresols with boiling points of 124 – 129 °C at 2.67 kPa which are returned to the alkylation reactor, and dimers, trimers, and possibly tetramers (*bp* 125 °C at 2.67 kPa) of isobutene, which are removed from the system. *m*-Cresol or *p*-cresol and isobutene are subsequently recovered by dealkylation of the di-*tert*-butylcresols at ca. 200 °C in the presence of such acidic catalysts as sulfuric acid. The individual cresols are then further purified by distillation. Their purity may exceed 99 % [342], [343]. Continuous operation of the butylation – debutylation process is described in [342] and [344–346]. The process is attractive not simply because it gives a very high yield of pure cresol, but also because it enables 2,6-di-*tert*-butyl-*p*-cresol (BHT), a widely used antioxidant, to be produced simultaneously.

If under suitable conditions *m*-/*p*-cresol mixtures are chlorinated with sulfuryl chloride [347], nitrosated with sodium nitrite [348], or condensed with (para)formaldehyde [349], [350], *m*-cresol reacts considerably faster, and *p*-cresol with a purity of 96 – 98 % can be isolated from the reaction mixture as a byproduct. These processes are exploited in practice.

1.6. Quality Specifications and Analysis

Cresols and their mixtures are commercially available in a wide range of grades and purities. They are characterized according to the following criteria [351], [352]:

- *Content of cresols, xylenols, and other phenols,* determined preferably by GC, e.g., according to ASTM 3626-80
- *o-Cresol content* (mixtures), determined via the crystallizing point of the cineole adduct according to [351], PC 17-67; or *m-cresol content* (mixtures), determined via the crystallizing point of the urea adduct according to [351], PC 16-67
- *Crystallizing point*, directly or after drying (pure isomers), e.g., according to [351], PC 10-67
- *Distillation range* (mixtures), e.g., according to [351], PC 5–67, or DIN 52 137 and 52 139
- *Residue on evaporation,* e.g., according to [351], PC 7-67
- *Residue on distillation,* e.g., according to [351], PC 6-67
- *Specific gravity,* e.g., according to [351], PC 2-67
- *Color* (color number), e.g., according to [351], PC 1-67, or ASTM D 3627
- *Water content,* determined either by azeotropic distillation with xylene according to Dean and Stark ([351], PC 3-67) or by the Karl Fischer method (ASTM D 1631-80)
- *Content of neutral oils,* e.g., as determined according to [351], PC 4-67, by distillation after addition of sodium hydroxide solution (cresolate formation)
- *Content of pyridine bases,* determined either according to [351], PC 4-67, by titrating the distillate from the neutral oil determination with hydrochloric acid, or by direct titration with perchloric acid in glacial acetic acid [352]
- *Total sulfur content,* e.g., according to [351], PC 22-67 (reduction method)
- *Acidity or alkalinity,* e.g., according to [351], PC 9-67, by titration against phenol red
- *Solubility in sodium hydroxide solution,* e.g., according to [351], PC 16-67

Specifications laid down in British Standards are as follows: For *o*-cresol (crystallizing point, *fp,* grade A 30.3 – 31.0 °C; grade B 29.3 – 30.3 °C; grade C 28.3 – 29.3 °C), *m*-cresol (*fp* $\geq$ 10.5 °C), and *p*-cresol (*fp* $\geq$ 34.0 °C) in B.S. 522 : 1964; for cresylic acid of specified *o*-cresol content (45 to 90 %) in B.S. 517 : 1964; for cresylic acid of specified *m*-cresol content (60 to 39 %, grades A to E) in B.S. 521 : 1964; and for so-called refined cresylic acid (grades A to E with altogether 0.5, 1.0, 2.0, 3.0, or 5.0 % water, pyridine bases, and neutral oil content) in B.S. 524 : 1964.

Maximal amounts of impurities encountered in commercially available cresols are usually no more than 0.2 % water, 0.15 % pyridine bases, 0.1 % neutral oils, and 0.01 % sulfur. Synthetic cresols are practically free from pyridine bases and sulfur. Pure cresols are colorless but may have a faintly yellowish color. Their mixtures sometimes have a slightly stronger tinge, ranging from yellow to brown.

o-Cresol is produced with a purity of 99.2 – 99.9 % (*fp* $\geq$ 30.7 °C), e.g., for ECN resins (see Section 1.8). Commonly used technical grades have purity levels of 98.2 – 99 % (*fp* $\approx$ 30.3 –30.6 °C), ca. 96 % (*fp* $\approx$ 29.5 °C), and ca. 94 % (*fp* $\approx$ 28.5 °C) and thus correspond to grades A, B, and C of the British Standard. For example, *m*-cresol, is sold at purities of 99 % (*fp* $\approx$ 11.5 °C), 98 % (*fp* $\approx$ 11 °C), and 96.5 % (*fp* $\approx$ 10 °C). *p*-Cresol usually has a purity of 99 % (*fp* $\approx$ 34 °C). Grades with a purity of ca. 95 % (*fp* $\approx$ 31 °C) and ca. 65 % are also available. The main impurity is *m*-cresol.

Technical cresol mixtures are usually classified according to their *m*-cresol content, which is between 20 and 70 %. Within this range, many different grades are supplied, depending on the manufacturer and the customer's requirements; there may also be substantial differences between them on the basis of phenols (phenol itself, *o*-cresol, *p*-cresol, xylenols, 2-ethylphenol, and other alkylphenols) that are additionally present, as well as other impurities (water, pyridine, neutral oils, and sulfur compounds). Thus, there are cresol mixtures containing up to 50 % phenol, or almost 50 % xylenols and other alkylphenols, or which have a total cresol content of only ca. 30 %; normally the latter lies between 60 and 90 %. *m*-/*p*-Cresol mixtures obtained by chlorotoluene hydrolysis or from the cymene – cresol process are distinguished by their high *m*-cresol content (70 % and 60 %, respectively)

and by their high total content of cresol, normally $\geq 99\,\%$.

1.7. Handling, Storage, and Transportation

The cresols are corrosive, and toxic if absorbed through the skin (see Chap. 4). Work with cresols should be carried out in closed apparatus wherever possible. The rooms must be well ventilated, and precautions, such as the use of airlocks and the gas compensation technique, must ensure that cresol vapor or dust cannot be inhaled by personnel. The fundamental criterion of the effectiveness of all such precautions is the MAK value or TLV, which in 1998 was fixed at 5 ppm (22 mg/m^3) for all cresol isomers and isomer mixtures. This level corresponds to the odor threshold. At higher concentrations, e.g., resulting from operational disturbances, suitable respirators must be worn. In addition, persons handling cresol must always have adequate eye protection and, if necessary, body protection, e.g., as provided by polychloroprene or PVC [poly(vinyl chloride)] gloves, long aprons, fully protective suits, etc. Further recommendations on the handling of cresols and xylenols may be found in [353–356] and in the safety data sheets of cresol manufacturers.

Steel vessels are suitable for storage. The discoloration that takes place on storage is promoted by elevated temperatures, light, oxygen, water, and catalysts, e.g., by dissolved iron or copper. If the product is required to remain colorless for as long as possible, it is best to use tanks of stainless steel (V4A; AISI 316Ti). If exceptional color stability is required, the product should also be stored under nitrogen. Access of moisture must be prevented, since cresols absorb water readily. Both *o*-cresol and *p*-cresol, which are solids at room temperature, have to be handled at a temperature higher than their crystallizing points. Cresol – air mixtures reach the lower explosive limit at ca. 76 °C in the case of *o*-cresol and at ca. 83 °C in those of *m*- and *p*-cresol; therefore, if the storage temperature exceeds 70 °C or 75 °C, respectively, the gas space must be rendered inert with nitrogen. Storage practice must comply with local regulations. The storage containers must be tested regularly for soundness and freedom from leaks. As the cresols are classified as water pollutants, measures such as the provision of tank basins must be taken to prevent cresol from entering the soil or drains.

Cresols are transported in heatable tank cars, in tank trucks, or in steel drums with a capacity of ca. 200 L. The container must bear the appropriate hazard warnings in compliance with the regulations. For unloading and sampling, see [355].

Transportation is subject to the following regulations:

International sea transport (IMDG Code) and international air transport (ICAO/IATA-DGR) for *o-, m-,* and *p*-cresol and cresol mixtures: Class 6.1, UN no. 2076, package group II; for cresylic acids: class 6.1, UN no. 2022, package group II. For transport of *o-, m-,* and *p*-cresol, cresol mixtures, and cresylic acids on European roads (ADR), railways (RID), and waterways (ADNR): Class 6.1, no 27b.

National regulations: United States DOT-CFR 49: § 172.101 class 6.1; for *o*-, *m*-, *p*-cresol and cresol mixtures: UN no. 2076; for cresylic acids: UN no. 2022. In Germany for the transport of *o*-, *m*-, and *p*-cresol, cresol mixtures, and cresylic acids on roads (GGVS), railways (GGVE), and waterways (GGVBinSch): Class 6.1, no 27b.

Cresols are liquids that are partly miscible with water and have flash points of 80 – 90 °C. As such, they are, therefore, classified in Germany as belonging to group A, hazard class III, according to the regulations for the storage of flammable liquids (Verordnung über die Lagerung brennbarer Flüssigkeiten, VbF). In the United States, *m*- and *p*-cresol belong to Category 1 of the NFPA 704M fire hazard classification system. Water fog, foam, dry chemical extinguishers, and – for small fires – carbon dioxide are suitable for fire fighting (never use a sharp jet of water). In Germany, VDE Specification 0171 places the cresols in Ignition Group T 1.

1.8. Uses

Most of the *o*-cresol manufactured in Europe is chlorinated to 4-chloro-*o*-cresol (PCOC), the starting material for the chlorophenoxyalkanoic acids 4-chloro-2-methylphenoxyacetic acid

(MCPA), 2-(4-chloro-2-methylphenoxy)-propionic acid (MCPP), and γ-(4-chloro-2-methylphenoxy)butyric acid (MCPB), which are important as selective herbicides. A considerably smaller proportion is nitrated to 4,6-dinitro-*o*-cresol (DNCO), which has both herbicidal and insecticidal properties, and is also used as a polymerization inhibitor for the production and distillation of styrene.

Highly pure *o*-cresol is increasingly processed, especially in Japan, to epoxy – *o*-cresol novolak resins (ECN resins), which are used as sealing materials for integrated circuits (chips). *o*-Cresol (of common quality) is also used to modify traditional phenol–formaldehyde resins.

o-Cresol is also important as a precursor of various dye intermediates, of which the most important in terms of quantity is *o*-cresotinic acid (*o*-hydroxymethylbenzoic acid) produced by the Kolbe synthesis. This acid finds further use in the manufacture of pharmaceuticals, whereas its methyl esters serve as dyeing auxiliaries.

An appreciable amount of *o*-cresol is used as a solvent, either directly or after hydrogenation to 2-methylcyclohexanol or 2-methylcyclohexanone. In the form of its carbonate ester, *o*-cresol constitutes a starting material in the synthesis of coumarin. The alkylation of *o*-cresol with propene gives carvacrol (3-isopropyl-6-methylphenol), which is used as an antiseptic and in fragrances. In addition, small amounts of *o*-cresol are, e.g., alkylated with isobutene and used as starting materials in the production of various antioxidants, for the production of components for thermal recording materials, and for pharmaceuticals (e.g., the muscle relaxant Mephenesin).

m-Cresol, either pure or mixed with *p*-cresol, forms a starting material for such important contact insecticides as *O,O*-dimethyl-*O*-(3-methyl-4-nitrophenyl)thionophosphoric acid (fenitrothion; Folithion, Sumithion) and *O,O*-dimethyl-*O*-(3-methyl-4-methylthiophenyl)thionophosphoric acid ester (fenthion; Baytex, Lebaycid). In addition, *m*-cresol is needed in the synthesis of phenyl *m*-tolyl ether (*m*-phenoxytoluene), which after oxidation to *m*-phenoxybenzaldehyde serves as a building block in the production of insecticides of the pyrethroid type.

Selective methylation of pure *m*-cresol with methanol gives 2,3,6-trimethyphenol, which is an important starting material for vitamin E synthesis; it also serves as a comonomer for the modification of poly(phenylene oxide) resins. Pure *m*-cresol also has considerable importance in the production of fragrance and flavor substances: its isopropylation gives thymol, from which (−)-menthol is obtained by hydrogenation and separation of the isomers. 6-*tert*-Butyl-*m*-cresol, obtained by alkylation of *m*-cresol with isobutene, is the starting material for the perfume fixative musk ambrette. The condensation of 6-*tert*-butyl-*m*-cresol with sulfur dichloride gives 4,4′-thiobis(6-*tert*-butyl-*m*-cresol), an important antioxidant for polyethylene and polypropylene. Further antioxidants are produced from 6-*tert*-butyl-*m*-cresol by condensation with butyraldehyde or crotonaldehyde. Pure *m*-cresol is also used for the production of positive photoresist compositions and for thermal recording materials. In Japan, *m*-toluidine is produced on demand by amination of *m*-cresol.

The 4-chloro-*m*-cresol obtained by selective chlorination of pure *m-cresol or m-/p*-cresol mixtures finds use as a disinfectant and preservative. 2,4,6-Trinitro-*m*-cresol can be used as an explosive.

p-Cresol, pure or mixed with *m*-cresol, is used mainly to produce 2,6-di-*tert*-butyl-*p*-cresol (BHT), a nonstaining and light-resistant antioxidant with a wide range of applications. 2-Alkyl-*p*-cresols obtained by the monoalkylation of *p*-cresol in the *ortho* position, e.g., *tert*-butyl-, cyclohexyl-, methylcyclohexyl-, α-methylbenzyl-, or nonyl-*p*-cresol, can be condensed with formaldehyde or sulfur dichloride to give 2,2′-methylene- or 2,2′-thiodiphenols, which are also important as antioxidants. 2,6-Dicyclopentyl-*p*-cresol, obtainable by dicyclopentylation of *p*-cresol, is a very effective antioxidant. Coupling of 2-*tert*-butyl-*p*-cresol with diazotized 4-chloro-2-nitroaniline yields Tinuvin 326, an absorber of UV light, which finds use, e.g., for polyethylene and polypropylene films and coatings. 2,6-Dinitro-*p*-cresol (DNCP) is used also (see above) as a polymerization inhibitor of styrene. In the fragrance industry, *p*-cresol is used to obtain *p*-cresolcarboxylic acid esters and, particularly, *p*-cresol methyl ether, most of which is used in the production of anisaldehyde, which is also important for the manufacture of 2-ethylhexyl-*p*-methoxycinnamate, a UV adsor-

ber in sunscreens, and for various pharmaceuticals, e.g., the coronary therapeutic Diltiazem and chemotherapeutics like trimethoprim. The direct oxidation of *p*-cresol gives *p*-hydroxybenzaldehyde, which is etherified to give anisaldehyde or is used for the production of the aroma chemical raspberry ketone and raspberry ketone acetate, which is used as a pheromone of the asian melon fly. Like *o*-cresol, *m*- and *p*-cresol are used as components of various dyes; the predominant intermediate here is 2-nitro-*p*-cresol.

An important field of application for technical cresol mixtures is the production of modified phenolic resins by condensation with formaldehyde. The suitability and price of cresol mixtures for this purpose depends on their content of *m*-cresol, the most reactive of the three isomers. Cresol mixtures are highly important as solvents for synthetic resin coatings (wire enamels).

m-/*p*-Cresol mixtures free of the *o* isomer are used to produce neutral phosphoric acid esters (tricresyl phosphate, diphenyl cresyl phosphate), which find use as fire-resistant hydraulic fluids, as additives in lubricants, as air filter oils, and as flame-retardant plasticizers for PVC and other plastics.

The bactericidal and fungicidal properties of cresols enable them to be used as disinfectants in soap. Synthetic tanning agents of commercial importance are obtained by the condensation of formaldehyde with cresolsulfonic acids and by the sulfonation of novolaks obtained from cresols. Crude cresols are used as wood preservatives. Cresol mixtures are also used in ore flotation and fiber treatment, as metal degreasing and cutting oils, as extracting solvents, and as agents for removing carbonization deposits from internal combustion engines. Methylcyclohexanol and methylcyclohexanone produced by hydrogenation of cresols are used in the paint and textile industries.

1.9. Economic Aspects

The combined total production of cresol in the United States, Europe, Japan, and South Africa in 1998 was estimated to be about 175 000 t; ca. 105 000 t of which was synthetic cresol, and ca. 70 000 t natural cresol.

About 42 000 t was produced in the United States, about 50 000 t in Europe, about 58 000 t in Japan, and about 25 000 t in South Africa. About 25 % of the total output is used by the manufacturers themselves. The so-called natural cresol comes from gasification of coal, from coking of coal and from spent refinery caustics in a ratio of about 50 : 35 : 15. Approximately 45 % of the total cresol output is processed in the form of pure *o*-cresol and pure *p*-cresol, and the rest as isomer mixtures. About 35 000 – 40 000 t of pure *m*/*p*-cresol mixture was separated – mostly by the butylation/debutylation-process – into pure *m*-cresol with coproduction of 2,6-di-*tert*-butyl-*p*-cresol (BHT).

The above figure for natural cresol from tars of coal gasification and coking and from spent refinery caustics refers only to the cresol content. It does not include the xylenols contained in the raw material (ca. 30 000 t), which to some extent are sold as though they were cresol.

The total output of cresol has diminshed in the last decade. Stagnating, partly declining markets, the entrance of 2,6-xylenol producers into the *o*-cresol market, the emergence of South Africa in the market for purified cresols, the declining availability of coal tars from coking processes and of spent refinery caustics, and the increasing environmental costs have, especially in the United States and in Europe, led to major industrial changes with restructuring, capacity reductions, and plant closures.

2. Xylenols [1–3]

Xylenol, dimethylphenol, $C_8H_{10}O$, M_r 122.166, occurs in six isomeric forms:

2,3-Xylenol
2,3-dimethylphenol
[*526-53-0*]

2,4-Xylenol
2,4-dimethylphenol
[*105-67-9*]

2,5-Xylenol
2,5-dimethylphenol
[*95-87-4*]

2,6-Xylenol
2,6-dimethylphenol
[*576-26-1*]

3,4-Xylenol
3,4-dimethylphenol
[*95-65-8*]

3,5-Xylenol
3,5-dimethylphenol
[*108-68-9*]

The numbering of the substituents normally and correctly begins from the OH group but is occasionally (erroneously) started from the methyl group: 2,4-xylenol can be referred to as 1,3,4-xylenol, 4-hydroxy-*m*-xylene, or 4-hydroxy-1,3-dimethylbenzene.

Xylenols are present, e.g., in the essential oils of various conifers, in tea, in tobacco and tobacco smoke, in roasted coffee, and in various smoked foods. In many cases, they contribute to the flavor of these products.

From the standpoint of economics, the most important isomer is now 2,6-xylenol, of which coal tar contains only a relatively small amount and which is therefore produced almost entirely by synthetic means.

2.1. Properties [1–3]

The xylenols are colorless crystallizing compounds that are soluble in alcohol, acetone, and in many other organic solvents. They are less soluble in water than the cresols. Except for 3,5-xylenol, their acidity is likewise lower than that of the cresols. They are soluble in aqueous sodium hydroxide, but to different extents, depending on the structure. Their chemical behavior is similar to that of the cresols. Physical data are presented in Table 4. For dependence of the thermodynamic data on temperature, see [9], [357–360]. Vapor – liquid equilibrium data of xylenols with numerous other substances are compiled in [20]. For the relationship between vapor pressure and association of xylenols, see [17].

2.2. Isolation

With regard to the formation of xylenols in various thermal cracking processes, see Section 1.3.

Xylenols, with the cresols and other phenols, are isolated from high-temperature, low-temperature, and Lurgi pressure gasifier coal tars (see Section 1.3.1) and from spent refinery caustics (see Section 1.3.2). The resulting crude phenols (cresylic acids) contain all six xylenols in amounts that differ greatly according to the raw material and conditions of formation (see Table 3). Moreover, the ratio of the xylenols themselves differs. In xylenols from spent refinery caustics, 2,4-xylenol generally predominates; besides this, the content of 2,5-xylenol is high, whereas that of 3,5-xylenol is relatively small [361]. Xylenols from bituminous coal tar are characterized by their high content of 3,5-xylenol. The average isomer ratio of bituminous coal tar xylenols is given in [362]; for example, as 31.9 % 3,5-xylenol, 28.1 % 2,4-xylenol, 14.1 % 2,3-xylenol, 13.6 % 2,5-xylenol, 6.9 % 2,6-xylenol, and 6.5 % 3,4-xylenol.

In the distillation of crude phenol, which is normally carried out continuously, the 2,6-xylenol present and some 2-ethylphenol enter the *m*-/*p*-cresol fraction. The other xylenols and the ethylphenols, as well as several C_9 phenols, are separated from the higher boiling phenols and the phenol pitch (→ Tar and Pitch) either together as a crude xylenol fraction or (in the case of xylenols from low-temperature tar) successively in the form of several differently enriched xylenol fractions.

2.3. Separation

For the isolation of individual xylenols, the crude xylenol fraction (see above) is rectified discontinuously into fractions of a narrow boiling temperature range [30].

2,4-Xylenol and 2,5-xylenol are contained in the fraction boiling at 208 – 212 °C at 101.3 kPa. The isomers are usually sold as a mixture. Since the difference between their boiling points (0.2 °C at 101.3 kPa) is too small for separation by distillation, other means of separation must be utilized.

If the fraction is cooled, the greater part of the 2,5-xylenol crystallizes and is then obtained in pure form after recrystallization. After sulfonation of the centrifuged mother liquor with 92 % sulfuric acid and dilution with water, the remaining 2,5-xylenol crystallizes as 2,5-xylenolsulfonic acid. Hot potassium chloride solution is then added to the filtrate, and

Table 4. Physical properties of pure xylenols

Physical property	2,3-Xylenol	2,4-Xylenol	2,5-Xylenol	2,6-Xylenol	3,4-Xylenol	3,5-Xylenol

the temperature is lowered. This precipitates the potassium salt of 2,4-xylenolsulfonic acid, from which, after recrystallization from water and acidification with sulfuric acid, the 2,4-xylenol is released by hydrolysis and stripped with steam.

It is also possible to separate 2,4- and 2,5-xylenol by butylation with isobutene. The process is used industrially in combination with the production of 6-*tert*-butyl-2,4-dimethylphenol. Due to the steric hindrance of the phenolic OH group, the resulting 6-*tert*-butyl-2,4-dimethylphenol cannot be dissolved in 10 % aqueous sodium hydroxide, whereas the 4-*tert*-butyl-2,5-dimethylphenol can. The unwanted of the products separated in this way can be debutylated with a catalytic amount of concentrated sulfuric acid. It has also been proposed that 2,5-xylenol be isolated by exploiting the fact that the two isomers have different butylation and debutylation rates on highly acidic ion-exchange resins [363], depending on temperature. 2,4-Xylenol and 2,5-xylenol can also be separated via adduct formation with phenols or amines [364].

Separation of 2,4-xylenol from its mixture with 2,5-xylenol (and *m*-ethylphenol) can also acchieved with an SrX zeolite as adsorbent and 1-hexanol as desorbent [365].

2,3-Xylenol is isolated from a fraction boiling at 215 – 218 °C by selective dephenolation with dilute aqueous sodium hydroxide, introduction of the free phenols into milk of lime, and stripping with steam; it can then be purified by recrystallization from benzene. It is also obtained in the cooling crystallization of a very narrow distillate fraction. Another method is the cooling crystallization of the distillation cut with *n*-

heptane at − 10 °C, which gives 3,5-xylenol in ≥ 99 % purity [366].

3,5-Xylenol is crystallized by cooling the fraction that boils at 218 – 221 °C, after which it is centrifuged and recrystallized from benzene.

3,4-Xylenol is obtained in the same way as given above from the fraction that boils at 223 – 225 °C; it is likewise centrifuged and recrystallized from benzene.

3,5-Xylenol or 3,4-xylenol can also be separated from other xylenols and from trimethylphenols via adduct formation with anhydrous calcium bromide [367].

Faujasite zeolites modified with copper or silver [368], potassium, barium, or lead [369] cations adsorb 3,5-xylenol less readily than other xylenols, thus enabling 3,5-xylenol to be separated as a raffinate component [368].

2,6-Xylenol has a boiling point ca. 0.9 °C lower than that of *p*-cresol at 101.3 kPa; the difference is ca. 4 °C at 20 kPa [9]. Thus, it can be obtained from the first runnings of the *m*-/*p*-cresol fraction. 2,6-Xylenol can be isolated in numerous ways. In the azeotropic distillation of the *m*-/*p*-cresol fraction with steam, 2,6-xylenol crystallizes from the condensate. 2,6-Xylenol can be distilled from cresolate caustics by virtue of its lower acidity, after which it is obtained from the condensate by extraction with benzene. For this reason, the condensate from the steam distillation of the crude phenolate caustic obtained from coal tar (see Section 1.3.1) is also suitable as a starting material for the isolation of 2,6-xylenol.

In fractions highly enriched with 2,6-xylenol, e.g., those obtained from synthesis by the methylation of phenol (Section 1.4.4), the 2,6-xylenol can be separated from *m*- and *p*-cresol and other phenols by countercurrent extraction with aqueous sodium hydroxide – hydrocarbon mixtures. This "dissociation extraction" technique takes advantage of the lower acidity of 2,6-xylenol. The product can be isolated from the hydrocarbon phase in a purity in excess of 98 % [370], [371]. Very high separation factors were obtained by dissociation extraction using solid anhydrous calcium hydroxide [372]. By comparison with *m*- and *p*-cresol, 2,6-xylenol has less tendency to form hydrogen bonds, and can therefore also be separated from the cresols either by countercurrent extraction with aqueous methanol–octane [373], by extractive distillation with di- or triethylene glycol [135], [181], [374], or alkanolamines [375]. Furthermore, the more polar phenols (cresols) can be distilled from the 2,6-xylenol as azeotropes with $C_{10} - C_{14}$ aliphatics as entrainers [376–378]. Cresols are adsorbed more readily than 2,6-xylenol on zeolites, e.g., of the K – Ba – X type; therefore, 2,6-xylenol can be isolated in high purity as a raffinate stream [379–381]. The isolation of 2,6-xylenol by the fractional crystallization of phenol methylation residues greatly enriched by distillation can be facilitated by adding phenol [382] or water [383], [384]. Good purification is achieved by crystallization under high pressure (e.g., 160 MPa at 75 °C) even in the absence of such additions [385]. Isolation of the 2,6-xylenol by distillation is possible if the *m*- and *p*-cresol impurities are selectively reacted with phosphorus oxide chloride to give phosphoric acid esters [386], with formaldehyde to give diphenylmethanes [387], with isobutene to give *o*-alkylated products [388], or with methanol on a catalyst either of Al_2O_3 [389] or of titanium sulfate–magnesium oxide [390] to give higher boiling xylenols and trimethylphenols.

2.4. Production

Phenol Methylation. Cresols or xylenols are formed in the methylation of phenol with methanol. Details of the catalysis and industrial conditions of the reaction are found in Section 1.4.4.

In the *gas phase, o*-cresol and 2,6-xylenol are the preferred products. The 2,6-xylenol can be made the main product if *ortho*-selective catalysts and high methanol : phenol ratios are used, and/or *o*-cresol is recycled [181]. As required under *ortho*-selective conditions, other products are chiefly 2,4-xylenol by methylation of *p*-cresol [391], and 2,3-xylenol [392] and 2,5-xylenol by methylation of *m*-cresol [393], [394].

For synthesis of 2,6-xylenol by selective *ortho*-methylation in the gas phase, phenol can be replaced by KA oil (a mixture of cyclohexanol and cyclohexanone from the oxidation of cyclohexane) if a magnesium-oxide-supported chromium oxide catalyst is used [395], [396].

With *liquid-phase* catalysts used for methylation (see page 16), it is typical not only that more 2,4-xylenol than 2,6-xylenol is formed, but also

that the purity of this 2,4-xylenol (ca. 90 %) is higher at the outset than that of the 2,4-xylenol obtained, e.g., from coal tars or spent refinery caustics (50 – 75 % purity).

Demethanization of Isophorone. 3,5-Xylenol, which is not normally a product of methylation processes and of which only a limited amount can be isolated in the pure form from natural xylenol mixtures, is produced in the United Kingdom by Inspec Fine Chemicals (formerly Synthetic Chemicals Ltd.) by demethanization of isophorone (3,5,5-trimethyl-2-cyclohexen-1-one) according to a process developed by Shell:

The reaction is carried out in the vapor phase in a multitubular reactor at 600 °C and 0.1 kPa and liquid hourly space velocities (LHSV) around 0.5 h^{-1}. This process, in which the isophorone conversion is practically complete, gives a 3,5-xylenol yield of ca. 70 % on a cobalt – molybdenum – potassium oxide–γ-aluminum oxide catalyst [397], or of ca. 80 % on a new rare-earth metal oxide–α-aluminum oxide carrier catalyst promoted with transition-metal oxides (0.1 % Co) and alkali metal oxides (0.4 % K) [398]. Toluene, xylene, mesitylene, dihydroisophorone, *m*-cresol, 2,4- and 2,5-xylenol, and 2,3,5-trimethylphenol are formed as byproducts. For selectivity improvement by alumina-supported K_2O/Cr_2O_3 or K_2O/V_2O_5 catalysts see [399], [400]. The catalyst has to be regenerated at intervals by burning off accumulated deposits of carbon. The carbon deposits are avoided in the process used industrially by Rütgers-VfT AG in Germany by carrying out the reaction at 520 – 540 °C and 10 – 15 bar in tubes of chromium–nickel steel with a packing of the same material. The yield is stated to be 65 % with an isophorone conversion of ca. 90 % [401]. Increased catalyst performance and throughput and diminished isophorone content of the product (< 3 %) is possible by using reaction zones containing catalyst with graduated reactivity and thermal stabilization (intercooling) of the process stream between the reaction zones [402]. At higher isophorone content the phenols from the condensed reaction product are separated from unconverted isophorone and other nonphenolic byproducts by extraction with sodium hydroxide solution and liberated with carbon dioxide [403]. The crude phenols are then rectified to give pure 3,5-xylenol. For 3,5-xylenol purification from mixtures with isophorone by addition of a tertiary amine (*bp* > 230 °C) followed by vacuum distillation to give azeotrope compositions from which 3,5-xylenol crystallizes, see [404].

Homogeneous catalysis is possible at 570 – 600 °C if ca. 1 wt % of methyl iodide (or another halogenated hydrocarbon) is added to the isophorone. Complete conversion is achieved at a liquid hourly space velocity (LHSV) of 0.5 h^{-1}. After the 3,5-xylenol has been worked up by distillation, it is obtained as a product of ca. 99 % purity in 85 % yield [405]. The iodine content of the product has to be lowered by heating with ca. 0.2 wt % of metallic zinc, magnesium, or iron before the distillation [406].

Isophorone is produced by alkaline trimerization of acetone (→ Ketones). The acetone can also be converted directly on a catalyst of either magnesium oxide [407] or chromium oxide – magnesium oxide – calcium silicate [408] at 470 °C and 0.5 kPa to give a mixture consisting essentially of 3,5-xylenol, isophorone, mesityl oxide, and unconverted acetone. High space – time yields of 3,5-xylenol are only possible if acetone and mesityl oxide are recycled and isophorone is manufactured as a coproduct [408].

Dimethylcumene Hydroperoxide Cleavage. According to the process of the Mitsubishi Gas Chemical Co. in Japan, 3,5-xylenol is obtained by oxidation of 3,5-dimethylcumene to 3,5-dimethylcumene hydroperoxide [409], which is then cleaved [410]. By comparison with the analogous cymene – cresol process (see Section 1.4.3), this method is more expensive, e.g., because the additional methyl group of the dimethylcumene leads to more side reactions (formation of more primary peroxide) and oxidation degrees of only ca. 10 % are economical. The 3,5-dimethylcumene is readily accessible by propylation of *m*-xylene in the presence of catalytic amounts of $AlCl_3$. The ratio of 3,5-

to 2,4-dimethylcumene at isomerization equilibrium is ca. 99 : 1 [411].

Alkaline Chloroxylene Hydrolysis. Under the conditions of the chlorotoluene–cresol process (see Section 1.4.2), chloroxylenes are hydrolyzed to xylenols. From 2,4- or 3,5-dimethylchlorobenzene, for example, one can obtain mixtures of 2,4- and 3,5-xylenol [412] that can be separated by distillation. The hydrolysis of 2,5-dimethylchlorobenzene under pressure leads to 2,5-xylenol. Similarly, the alkaline hydrolysis of 2,3- and 3,4-dimethylbromobenzene gives 2,3- and 3,4-xylenol [413].

Alkali Fusion of Xylenesulfonates. The toluenesulfonic acid – cresol processes (see Section 1.4.1) also give xylenols if xylene is used as the starting material instead of toluene. Thus, the sulfonation of *m*-xylene with 95 % sulfuric acid (4 h at 150 °C) or chlorosulfuric acid (1 h at 50 °C) yields a product consisting primarily of 2,4-dimethylbenzenesulfonic acid, the fusion of which with sodium hydroxide at 320 °C leads to 2,4-xylenol in 79 % yield [414]. If the sulfonation mixture is heated to a temperature of up to 220 °C, the 2,4-dimethylbenzenesulfonic acid isomerizes to the thermodynamically more stable 3,5-form, the fusion of which with excess alkali gives 3,5-xylenol [415]. If the 2,4-/3,5-dimethylbenzenesulfonic acid mixture is heated with water (steam) to 140 – 160 °C, the 2,4-dimethylbenzenesulfonic acid is selectively hydrolyzed; in the following alkali fusion, the residual 3,5-dimethylbenzenesulfonic acid is converted into 3,5-xylenol of 97 – 98 % purity [416] in a yield of ca. 70 %, based on converted *m*-xylene [68].

The sulfonation of *p*-xylene with 98 % sulfuric acid at 140 °C gives 2,5-dimethylbenzenesulfonic acid. Fusion of this with alkali metal hydroxide at 330 – 340 °C gives 2,5-xylenol in 80 % yield, based on *p*-xylene [417], [418].

3,4-Dimethylbenzenesulfonic acid, which is accessible in ca. 98 % yield by sulfonation of *o*-xylene with 96 % sulfuric acid at ca. 150 °C [419], [420], gives 3,4-xylenol in more than 90 % total yield when fused with alkali metal hydroxide at 320 – 330 °C [419]. Under kinetically controlled (mild) sulfonation conditions it is also possible to obtain some 2,3-dimethylbenzenesulfonic acid, and therefrom some 2,3-xylenol.

The alkali fusion of xylenesulfonates is used industrially, e.g., by Inspec Fine Chemicals in the United Kingdom (for 2,5-xylenol and 3,4-xylenol) and by the Taoka Chemical Company in Japan (for 2,3-xylenol and 3,4-xylenol).

Other routes to the xylenols include the Gulf oxychlorination process, nucleus hydroxylation (see Section 1.4.5), and oxidative decarboxylation of dimethylbenzoic acids [244], boiling the diazonium salts of xylidines [421], hydrogen peroxide oxidation of dimethylbenzaldehydes [422], oxidation of 2,4,6-trimethylphenol to 3,5-dimethyl-4-hydroxybenzaldehyde, which is decarbonylated to 2,6-xylenol [423], or hydrogenation of 2-*N,N*-dialkylaminomethyl-4-methylphenol (obtained from *p*-cresol, dialkylamine, and formaldehyde) to give 2,4-xylenol [424].

2,4-Xylenol was also obtained by hydrogenation of bis-[hydroxy(methyl)phenyl]methane, which was obtained by condensation of *o*-cresol with formaldehyde [425].

2,3-Xylenol can be produced by hydrogenation and debutylation of 3,5-di-*tert*-butyl-2-hydroxy-6-methylbenzyl acetate, which is obtained from 4,6-di-*tert*-butyl-3-methylphenol, formaldehyde, and acetic acid [426].

Isomerization. Xylenols for which there is inadequate demand and xylenol fractions from which certain xylenols have already been isolated can be isomerized catalytically. Aluminum oxides or silicates, the activities of which have been further increased with hydrogen fluoride, titanium dioxide, iron oxide, and other metal oxides [427–431], are suitable as catalysts. The equilibrium distribution of the xylenols (2,3 : 2,4 : 2,5 : 2,6 : 3,4 : 3,5-isomer) after their isomerization in the vapor phase at 340 °C on aluminum silicate is given as 9 : 30 : 24 : 11 : 12 : 14 [431]. In the liquid phase at 105 – 130 °C with aluminum chloride in combination with hydrogen chloride as catalyst, 3,5-xylenol is primarily formed [235]; however, uneconomically large amounts of $AlCl_3$ are consumed. With regard to isomerization with $HF - BF_3$, see [432]. If phenol [235] or an aromatic solvent such as benzene is present, transmethylation occurs, with the simultaneous for-

mation of cresol or toluene (see page 16). A recycling process for the preparation of 3,5-xylenol by separating it from the distilled isomer mixture with KX zeolite as adsorbent (*n*-hexanol as desorbent) and isomerizing the residual mixture again with silica – alumina at 400 °C in the presence of phenol, cresol, and trimethylphenol is described in [433].

2.5. Quality Specifications and Analysis

The xylenols are characterized according to the same methods of analysis as are used for cresols (see Section 1.6).

The fraction sold as a 2,4-/2,5-xylenol mixture is a clear yellow liquid that contains ca. 50 – 75 % 2,4-xylenol and ca. 30 – 10 % 2,5-xylenol, depending on its origin. The main impurities are *m*- and *p*-cresol and ethylphenols. 2,4-Xylenol from the methylation of phenol on liquid-phase catalysts (UK-Wesseling) has contained more than 89 % 2,4-xylenol and less than 7.5 % 2,5-xylenol. Pure 2,4-xylenol is offered with a content of ca. 97 % (*fp* 23.0 °C). 2,3-Xylenol and 2,5-xylenol are available with purities of ca. 97 % and ca. 98 %, respectively. 2,6-Xylenol is traded at purities of greater than 99.5 %, 98 – 99 %, 96 – 98 %, and 90 – 96 %. 3,4-Xylenol is available in the grades "technically pure" ($\geq$ 95 %; *fp* $\geq$ 62.2 °C) and "pure" ($\geq$ 98 %; *fp* $\geq$ 64 °C). 3,5-Xylenol is commercially available in purity grades of 95 % (*fp* 60.3 °C) and 99 % (*fp* 62.5 °C).

Xylenol mixtures differ widely in composition, depending on the manufacturer and the requirements of the customer. For example, there are xylenol mixtures (cresylic acids) that contain almost 50 % cresol or 50 % higher alkyl phenols (C_9 and higher). The mixtures may also contain considerable amounts of ethylphenols in addition to the xylenols, depending on their origin. A rough classification is possible according to the distillation range (5 – 95 %), which could be, for example, 200 – 220 °C, 205 – 215 °C, 210 – 225 °C, 220 – 240 °C, 220 – 255 °C, or 230 –240 °C.

2.6. Handling, Storage, and Transportation

The xylenols are similar to the cresols in their physiological behavior. Their handling, storage, and transportation are, therefore, subject to the precautions applicable to cresols (see Section 1.7). This also applies to the precautions taken to prevent discoloration (storage and transportation in vessels of stainless steel, protection from light and moisture, and possible storage under nitrogen). References to the handling of xylenols are made in [353–356].

Xylenols and their mixtures are transported in ca. 200-L steel drums. Large volumes are shipped in liquid form by road or railway tank cars and export containers, which in the case of the pure isomers must be thermostated at a temperature above their melting point. They must be filled and transported under nitrogen. The shipping containers must bear the appropriate hazard warnings in accordance with the regulations.

The transportation of xylenols and xylenol mixtures is subject to the following regulations:

International sea transport (IMDG Code) and international air transport (ICAO/ATA-DGR): Class 6.1, UN no. 2261, packaging group II. Transport on European roads (ADR), railways (RID), and waterways (ADNR): Class 6.1, no. 14b.

National regulations: United States DOT-CFR 49: § 172.101 class 6.1, UN no 2261. With regard to their transportation on roads (GGVS), railways (GGVE), and waterways (GGVBinSch) in Germany, these products belong to class 6.1, no. 14b.

According to "Verordnung über brennbare Flüssigkeiten" (VbF), the properties and flash points ($\geq$ 86 °C) of xylenol mixtures and xylenols place them in group A, hazard class III (inasmuch as they are liquids). Water fog, foam, dry extinguishers, and, for small fires, carbon dioxide are suitable for fire fighting.

2.7. Uses

Xylenol mixtures are used as solvents (e.g., for wire enamels), disinfectants (e.g., in sheep dips), textile auxiliaries, and in ore flotation. Mixtures, particularly if they are rich in 3,5-xylenol and xylenols with two hydrogen atoms in the *o*- and/or *p*-positions, are used in the manufacture of xylenol – formaldehyde resins. Xylenols without an *o*-methyl group are used to produce nontoxic plasticizers and trixylenyl phosphates that serve as fire-resistant hydraulic fluids.

2,3-Xylenol is only used in small amounts, e.g., for the production of a pesticide.

2,4-/2,5-Xylenol mixtures constitute raw materials for antioxidants, especially those intended for gasoline (e.g., 6-*tert*-butyl-2,4-dimethylphenol) and rubber [e.g., 2-methyl-1,1-bis(2-hydroxy-3,5-dimethylphenyl)propane]. Pure 2,5-xylenol is used for the manufacture of pharmaceuticals, e.g., lipid reducers like gemfibrozil.

2,6-Xylenol is used primarily to produce poly(phenylene oxide) (PPO) resins, which are distinguished by high impact resistance, thermal stability, fire resistance, and dimensional stability. Oxidation of 2,6-xylenol gives 2,6-xylenol dimer, a speciality monomer to produce epoxy resins for encapsulating advanced semiconductors. 2,2-Bis(4-hydroxy-3,5-dimethylphenyl)propane (tetramethylbisphenol A), obtained by the condensation of 2,6-xylenol with acetone, serves as an intermediate for polycarbonates whose properties are similar to those of the PPO resins. 2,6-Xylenol is also treated with ammonia to yield 2,6-dimethylaniline, which is used especially in pesticide manufacture, [e.g., the fungizide metalaxyl (Ridomil) and herbizide metazachlor (Butisan S)] but also for the production of pharmaceuticals, e.g., local anesthetics like lidocain. Smaller amounts of 2,6-xylenol are used in the formation of pesticides, and in the manufacture of disinfectants as well as the antioxidant bis(4-hydroxy-3,5-dimethylphenyl)methane.

3,5-Xylenol is used in the production of various pesticides, e.g., 3,5-dimethyl-4-methylthiophenyl methylcarbamate (methiocarb, Mesurol), a broad-spectrum insecticide, acaricide, and molluscicide. 3,5-Xylidine, obtained by amination, is used particularly for perylene pigments. Alkylation with methanol gives 2,3,5-trimethylphenol, which can serve for the production of vitamin E. After chlorination to 4-chloro- and 2,4-dichloro-3,5-dimethylphenol, 3,5-xylenol is used as a disinfectant and industrial preservative. Other xylenols or xylenol mixtures likewise serve as disinfectants after chlorination.

3,4-Xylenol is the starting material for the insecticide 3,4-dimethylphenyl methylcarbamate (MPMC, Meobal).

Pure xylenols, besides the use for pharmaceuticals, are also used in small amounts in the synthesis of dyes, and fragrances.

2.8. Economic Aspects

As a rough estimate, the total output of xylenols in the United States, Western Europe, and Japan in 1998 was ca. 165 000 t. Xylenol mixtures accounted for ca. 30 000 – 40 000 t, 2,6-xylenol for ca. 125 000 t, and the remaining individual isomers (especially 2,4-, 2,5- and 3,5-xylenol), obtained by synthesis or isolated from mixtures, for ca. 10 000 t.

The xylenol mixtures are obtained – mainly in the United States, South Africa and Europe – from spent refinery caustics and coal tars. The production of xylenol by synthesis is accounted for by the United States, Europe, and Japan in the approximate ratio 54 : 24 : 22.

3. Environmental Protection

Cresols and xylenols are readily degradable biologically; the xylenols are degraded somewhat slower than the cresols [434]. Biological treatment plants with suitably adapted bacteria are able to degrade wastewaters with 900 mg of cresol/L and more [435].

In the environment, cresols are degraded at low concentrations, especially by bacteria that are widely distributed in the soil and water (particularly *Pseudomonas* species). Degradation by other organisms, including yeasts, fungi, algae, and higher plants, as well as by photolysis (half-life in air < 1 d), is also known [436]. Accordingly, these compounds do not persist in the environment [437], [438].

However, as cresols and xylenols show high acute toxicity both toward fish (96 h LC_{50} 1 – 10 mg of cresol/L) and to aquatic invertebrates, and as they impair the taste of edible fish and drinking water even in very low concentrations [436], [438], [439], the release of these compounds into surface waters is subject to strict limitations. Therefore, leaked or spilled cresols or xylenols must be prevented from entering surface waters or groundwater.

Liquid products can be adsorbed, e.g., with sawdust, peat, earth, kieselguhr, or other adsor-

bents, and then burned completely in special incineration plants. Solidified products should not be dissolved, but removed mechanically. Final residues can be neutralized with 2 – 3 % aqueous sodium hydroxide and flushed with plenty of water into suitable drains leading to a biological wastewater treatment plant.

Cresols and xylenols can generally be removed from production wastewater by extraction, e.g., with diisopropyl ether, butyl acetate, methyl isobutyl ketone, or toluene [440], to such an extent that the residual contents can be eliminated without difficulty in a biological wastewater treatment plant. The wastewater should enter the biological treatment plant continuously, not intermittently in batches.

The phenolic constituents of wastewater can also be removed to a very large extent with ion-exchange resins or such adsorbents as activated carbon [71], which can be subsequently regenerated, or with oxidizing agents such as hydrogen peroxide [441] or ozone [442], [443]. Stripping with steam is likewise possible, but is less effective.

Cresols and xylenols can be removed from waste gas streams by scrubbing with dilute aqueous sodium hydroxide or by incineration. Another effective method is adsorption on activated carbon, which is able to accumulate up to 0.5 kg of cresols/kg. The adsorbate is subsequently recoverable when the activated carbon is regenerated [444].

In the United States the cresol isomers and cresylic acids are classified as hazardous air pollutants (HAPs) in Title III of the 1990 Clean Air Act Amendements. Therefore, producers and users of cresols and cresylic acids must follow suitable operating procedures and install emission control equipment that follows the maximum achievable control technology (MACT) regulations of the US Environmental Protection Agency (EPA).

4. Toxicology and Occupational Health

Cresols and xylenols burn the skin and mucous membranes through degradation of proteins, similarly to phenols. Initially white, and later brownish black necroses appear on the skin. Certain individuals may show hypersensitivity symptoms in addition to the corrosive effect [353], [354].

Cresols and xylenols, like phenol, are toxic when absorbed through the skin. Their TLV or MAK value (5 ppm) is therefore supplemented by the word "skin" or the letter H (standing for the German word *Haut*). This percutaneous effect is easily overlooked because the initial burning sensation is followed by local anesthesia. The compounds are absorbed particularly rapidly when in the liquid form or dissolved (diluted). Even if only a relatively small area of the skin is exposed, e.g., a single arm or hand, there may be severe injury to health, possibly developing into a lethal paralysis of the central nervous system. Corresponding amounts of cresol or xylenol that are taken up through the respiratory tract, as vapor or as droplets, or through the stomach also cause severe poisoning in addition to corrosion. Systemic damage to liver and kidneys is possible. The initial or consecutive symptoms of poisoning are headache, dizziness, ringing in the ears, nausea, vomiting, muscular twitching, mental confusion, and loss of consciousness, depending on severity.

As phenols are rapidly absorbed through the skin and a causal treatment of the poisoning does not yet exist, rinsing them off the skin (not wiping them off) as soon as possible constitutes a decisively important first aid measure. A mixture of polyethylene glycol and ethanol in a 2 : 1 ratio has thus far proven most suitable for this purpose: it should be kept available for rapid use at the workplace in portable pressure vessels (similar to fire extinguishers, but painted a different color, e.g., green) [353]. Polyethylene glycol 400, or water, is less suitable, particularly in the case of xylenols, which are less soluble and may solidify on the skin. Water in very large quantities should only be used if no other solvents are immediately available. Eyes should be rinsed only with water, but very thoroughly, for at least 15 min. If cresols or xylenols enter the stomach, a large amount of water should be given immediately in small portions to achieve a diluting effect and, in addition, medicinal charcoal (1 tablespoon to 1 glass of water). Medical attention must be given, without delay, in every case. Further information on the prevention of accidents with cresols and xylenols, as well as the steps that should be taken if accidents occur, will be found in [353], [356].

Table 5. Some acute toxicity data for cresols and xylenols (LD_{50}, mg/kg)

	RTECS No.	Oral		Skin	
	[452]	Rat	Mouse	Rat	Rabbit
o-cresol	G06300000	121	344	620	890
m-cresol	G06125000	242	828	1100	2050
p-cresol	G06475000	207	344	750	301
2,4-xylenol	ZE5600000	3200	809	1040	
2,5-xylenol	ZE5775000	444	383		
2,6-xylenol	ZE6125000	296/1750	450/980	2325	1000
3,4-xylenol	ZE6300000		400		
3,5-xylenol	ZE6475000	608/3620	477/620	2400	2000

Prolonged contact with cresols or xylenols at concentrations that, although low, are above the MAK value (5 ppm) may result in absorption through the skin, mucous membranes, and respiratory organs, and cause gastrointestinal disturbances (vomiting, loss of appetite), nervous disorders, headache, dizziness, fainting, and dermatitis.

According to epidemiological investigations [445], cresols are not carcinogenic. A carcinogenic effect would indeed be surprising, since *p*-cresol, for example, is a normal product of human metabolism. Cresols have likewise caused no carcinomas in animal experiments [436], [446]. In the *Salmonella* microsome test, all three cresol isomers have been found to be nonmutagenic toward the most widely differing *Salmonella* strains, both in the presence and in the absence of hamster or rat microsomal fractions [447]. The sister-chromatid exchange mutagenicity tests of the cresol isomers revealed no dose-dependent effects either in vitro in cultured human fibroblast or in vivo in male mice [448]. Toxicological evaluations, of 2,4-xylenol, 2,6-xylenol, and 3,5-xylenol [449], have shown no mutagenic activity, and the available carcinogenicity studies are inconclusive.

Extensive literature compilations on the toxicity of the cresols may be found in [436], [450], [444], which also contain some information on the xylenols, and in [446], [451]. For 2,4-, 2,6-, and 3,5-xylenol, see [449]. Toxicity data for cresols and xylenols are summarized in [452–454]. Some acute toxicity data are compiled in Table 5.

1. Agricultural Aspects

Crop protection, one of the elements of agricultural production, is an integral feature of complex ecological and economic systems. The goals of crop protection, from the aspects of farm economics and ecology, are to prevent preharvest losses, i.e., to safeguard crop yields; assure quality; replace labor-intensive methods; and contribute to the development of new agricultural production systems in spite of constraints of climate or soil. Crop protection is an essential element of integrated crop production. It plays an important role in environmentally adapted and technologically advanced farming systems [1]. By their very nature, crop protection and nearly all other agricultural disciplines are mutually dependent. This applies to the natural sciences, including ecology, and equally well to the economic and technical aspects of agronomy.

1.1. Ecological Conditions

Agriculture is always characterized by deliberate intervention in ecological systems. Its goal is to replace existing plant societies with crops giving optimum yields. This is possible only if farming techniques are adapted to environmental conditions, ecological influences opposing the agricultural goal are restrained, and ecological conditions themselves are controlled with reference to the agricultural purpose. Agriculture can therefore be seen as ecological management intended to achieve economically optimum yields.

Soil. The most important factor in agricultural production is the soil. A central concern of soil utilization is the long-term maintenance and, if possible, increase of fertility.

Historically, agriculture provided at first for satisfactory yields by cultivation of locations favored by nature. Soil nutrients, soil structure, and terrain were decisive in the separation of land into farming and nonfarming areas. When it was experienced that soil was impoverished by the removal of nutrients through crop harvesting, an attempt was made to compensate by employing the fallow, crop rotation, fertilization with stable manure, and variation in farming systems. Nevertheless, yields in Europe during the 19th century would have sharply deteriorated through soil exploitation if ecochemistry had not achieved decisive breakthroughs. The work of Liebig (1803 – 1873) demonstrated that fertility, balance of soil nutrients, and removal of nutrients by harvesting are all closely related. This knowledge has become the ecological foundation of husbandry. Well-balanced mineral fer-

10.1002/14356007.a08_061

tilization has since become an established element in good agricultural practice. In addition, it has contributed to ecological equalization: in earlier times, light soils (with a high percentage of sand) were considered less fertile; heavy soils (with a high percentage of loam) were sometimes viewed as difficult although fertile. The addition of nutrients made it possible to compensate for these inequalities and even poorer soils have become suited to the cultivation of wheat.

Fertilization and Cultivation. With regard to crop protection, ecological changes arising from variations of intensity in land use have had important consequences. Increases in yield made possible by the application of mineral fertilizers have generally increased \011 the production of biomass; this biomass usually remains in the field, except for the harvest. Therefore, the proportion of organic substances in the soil, resulting in humus formation, has steadily increased. At the same time, this makes it possible to utilize high-yielding varieties. In addition, quality may be improved, e.g., the baking characteristics of wheat or the brewing quality of barley. Improved soil productivity also makes it possible to manage much denser stands of crops and eliminate the fallow period. Crop rotation is therefore organized less with respect to yield than in accordance with economic and ecological considerations.

All these developments have a direct or indirect effect on plant protection. Only seldom is it possible through plant breeding to combine high yield potential and high resistance to plant diseases in the same variety, and many high-yielding varieties show increased susceptibility to disease. A higher crop density, for example in cereals, leads to changes in the microclimate, which is mostly wetter and somewhat warmer than in a thinner stand. Therefore, the conditions of propagation and infection become more favorable for fungal pathogenic agents, with more serious infestation. On the other hand, densely planted crops compete more vigorously with weeds, and late weed development is suppressed. The elimination of fallow periods and the simplification of the crop rotation cycle, especially with cereals, correspondingly increases the danger of infestation by harmful organisms, such as cereal aphids, cereal powdery mildew, nematodes, and others.

Overall it may seem that the ecological changes which have developed through modifications in agricultural practices, i.e., by increased intensity of soil utilization, have increased the problems of plant protection. However, these changes are not generally related to worsening of damages. In Europe, for example, some very ancient and serious problems have lost practically all significance. Prominent examples are the plagues of locusts, which were very important until the beginning of the 19th century but have now disappeared [2]. The loss in significance of grain ergot (*Claviceps purpurea*) should also be mentioned here, although this has now reappeared with the development of organic farming.

In many cases, a greater demand for plant protection has resulted directly from increased acreage. This applies, for example, to soybeans, of which an average of 28×10^6 ha were grown worldwide during the years 1961 to 1965; in 1984, this acreage, at 52×10^6 ha, had almost doubled.

Migration of Pest Organisms. The transmission of harmful organisms from one continent to another is one of the ecological phenomena that were formerly less significant but have become more important with ever shorter transportation times accompanying the development of international trade. The ecological aspect of these phenomena results from the fact that species introduced into new areas are not confronted with their natural biotic factors of limitation. Consequently their propagation potential can develop fully in their new home, being subject only to climatic conditions. Figuratively speaking, the ecosystem lacks an "immune reaction" in the newly infested areas. Examples of the introduction of harmful organisms with disastrous economic consequences are: the Hessian fly (*Mayetiola destructor*) brought to America from Europe; the migration of the cotton boll weevil (*Anthonomus grandis*) from Mexico to the southern states in the United States; the introduction of the European pine sawfly (*Neodiprion sertifer*) and the gypsy moth (*Lymantria dispar*) into North America from Central Europe; the grape vine louse (*Phylloxera vitifoliae*), the Colorado potato beetle (*Leptinotarsa decemlin-*

eata), and the San-José scale (*Quadraspidiotus perniciosus*) brought to Europe from America; the coffee rust (*Hemileia vastatrix*), introduced into South America from Africa; and many others [3]. In all these cases, basic ecological changes occurred, with direct economic effects on agricultural enterprises.

1.2. Economic Conditions

Agriculture produces about 95 % of the foodstuffs for the world population. The remaining 5 % is provided by fishing, hunting, and gathering. Tillage or cultivation of permanent crops occupies 11 % of the earth's land surface, meadow and pasture land 23 %. In sum about one-third of the land surface above sea level is utilized for agriculture. Employment of the working population of the world in agriculture is about 43 % [4]. These average figures do not provide a complete picture. In the developed countries, only 7.1 % of the working population is engaged in agriculture (e.g., Japan, 8.6 %; France, 7.1 %; Federal Republic of Germany, 3.1 %; and United States, 1.8 %). In the developing countries, the figure is 55.8 % (e.g., Niger, 85.2 %; India, 60.2 %; Egypt, 48.8 %; and Brazil; 35.1 %). In the developed countries, on the average, 7.1 persons work 100 ha of tillable land; in the developing countries, the figure is 68.5. The developed countries produce 35 % of the cereal yield on 23 % of the cereal acreage in the world; the developing countries produce 29 % of the yield on 44 % of the acreage; the centrally planned economies produce 36 % on 33 % of the acreage. The traditional classification of countries as agrarian and industrialized is therefore outdated. It is rather the case that the industrialized countries produce agrarian surpluses with a small labor force whereas the agrarian countries, with a large labor force and large acreage, often do not produce enough to meet their own needs. The reason is that the developed countries have succeeded in rapidly transforming agricultural science into practice. In Germany, for example, this resulted in wheat yields that, between 1800 and 1910, increased on the average from 1.0 t/ha to 2.0 t/ha; by 1950, this figure was 3.0 t/ha; and by 1984, it had reached 6.3 t/ha [2], [4]. These increases were due to the use of mineral fertilizers and plant breeding, and improvements in infrastructure, tillage, mechanization, and plant protection [5]. These influences are all interdependent and the importance of each cannot be measured separately from the others.

By definition, plant protective measures are limited in their effect to the prevention of loss and, therefore, can increase yields only indirectly. This has great economic significance for the farmer, for national import – export planning, and for world trade policies.

Crop Losses. For the individual farmer, crop losses usually occur when fixed costs (buildings, machines, debt service) and variable costs (seed, fertilizer, labor) have already been met; the cost/profit ratio deteriorates accordingly. With a profit margin of 10 %, a crop loss of 5 % reduces the net profit by half. In addition, losses of quality may be crucial (see Section 5.2.3).

Within national economic systems, crop damage may have considerable importance, especially where cash crops are a vital source of foreign exchange. For example, the collapse of the coffee industry in the last century in Ceylon (Sri Lanka) caused by coffee rust (*Hemileia vastatrix*) had far-reaching consequences. In Ghana, Nigeria, and the Ivory Coast Republic during the 1950s, a combination of a virus infection (swollen shoot disease) and a fungal infestation (*Phytophthora palmivora*) caused by cacao bugs (*Miridae*) destroyed 220 000 t of cocoa annualy, more than half of a good harvest. A similar catastrophe, caused by the cotton boll weevil (*Anthonomus grandis*), overtook the cotton industry of the southern United States around the turn of the century. The consecutive epidemics of grapevine powdery mildew (*Uncinula necator*) and grapevine downy mildew (*Plasmopara viticola*), together with the introduction of the grape vine louse (*Phylloxera vitifoliae*), were disastrous for European viniculture in the 19th century. In all such cases, in which whole sectors of the economy are dependent on a single crop, its sudden loss has far-reaching consequences. Destruction of basic foodstuffs by swarms of locusts repeatedly caused famine in medieval Europe [6]. In India, a rice fungus had similar results [5]. More recent examples are the failure of the potato crop in Ireland in 1845 – 1849 and in Germany in 1916 – 1917, caused by the potato blight (*Phytophthora infestans*) [7], [8].

More significant, however, than such catastrophes are the regular hidden losses caused by

insect pests, plant diseases, and competition by weeds. On the average, these amount to a good third of the potential harvest of the 60 crops of international importance [5], [9], constituting thereby a prime factor in the world economy and at the same time an enormous food potential. Even a partial prevention of these losses would substantially extend the generally meager world nutritional base. In comparison to more ambitious projects, this would also lead to a low cost increase in food production, and lower prices. With respect to the limited purchasing power of many developing countries, this would be an important factor.

In addition, harvest fluctuations caused by harmful organisms complicate budgetary calculations.

A good example of international consequences is seen in the variation in the import requirements of the Soviet Union and the corresponding effect on the U.S. agrarian economy.

2. World Food Supply

The world food supply is very unevenly distributed. Agricultural overproduction in some developed countries is in contrast to the deficit in many developing countries that lack the buying power and infrastructure that would make a better distribution of the surplus possible [10]. The problem of world nutrition of course transcends distribution: even with a completely equal distribution of the foodstuffs currently produced, there would be a deficit of 10 – 18 %. Even with good harvests, world grain reserves seldom exceed a one-month supply (measured by market capacity); since the early 1950s reserves have often fallen below a ten-day supply. Seen in this light, world food reserves are marginal. It is of course true that the great flexibility of American agriculture permits production to be increased considerably and quickly to meet shortages in regions with ample purchasing power. On the other hand, world supplies are heavily dependent on a few countries. Export surpluses of grain have so far been produced only by the United States, Canada, Australia, and Argentina. A single harvest failure in the United States caused for example by an epidemic of fungus, would create a world nutritional crisis.

Production. Overproduction is of prime political and economic interest in some developed countries. In its historic context, this development is extraordinary. For the first time in its history, Europe has an oversupply rather than a shortage of food. Since ancient times, the search for agriculturally productive regions has had decisive political consequences, including, for example, the extension of the Roman Empire to North Africa, the migration of Germanic tribes during the 4th century A.D., and the eastward expansion of the German Empire since the Middle Ages. The same is true of past colonial policies, such as those of the French in Algeria, Tunisia, and Morocco. Following the discovery of America, the various waves of westward emigration from Europe were driven to a large extent by shortages of food and land.

Until long after 1945, Europe was dependent on agricultural imports. In the European Community, the current overproduction in some commodities (wheat, sugar, milk products) and the near self-sufficiency in others (cereals other than wheat, potatoes, vegetables, and meat) represent a historical novelty. Problems of supply have been replaced by those of commercial utilization. This situation is aggravated by the serious agrostructural problems of small farms for which it is difficult to find political and social answers. Part of the overproduction results from the importation of fodder such as soybean products. If the production of foodstuffs in the Federal Republic of Germany that depends on foreign fooder is not taken into account, the degree of self-sufficiency in 1983/84 would be reduced from 95 % to 78 % [11].

However, abundance in the industrialized countries tends to stabilize prices, especially those of foodstuffs, which are thus made more available even to countries with limited purchasing power. Producer price indices for U.S. crops rose from 100 to 146 points between 1977 and 1984; at the same time, agricultural production costs rose from 100 to 155 points. In the Federal Republic of Germany, the comparable index for crops rose from 100 in 1977 to 108 in 1984 and for production costs from 100 to 148 [4]. This price pressure forces farmers to increase efficiency further.

Food production has risen considerably, as seen in the following figures in which the aver-

age production of 1974 – 1976 is taken as 100 [4]:

	1972	*1984*
Developed countries	92.1	113.7
Developing countries	90.1	133.0
World	91.3	122.7

As a result of a sharp growth in world population, however, the increase in per capita food supply is smaller (1974 – 1976 = 100):

	1972	*1984*
Developed countries	94.6	106.4
Developing countries	96.5	111.8
World	96.6	104.9

Regional data vary considerably as shown by the following figures for per capita supply of agricultural products for the developing countries of the respective regions (1974 – 1976 = 100):

	1972	*1983*
Africa	102.3	88.7
Latin America	96.7	103.4
Near East	98.7	94.2
Far East	94.3	111.9
Others	99.3	100.6

In contrast to these unfavorable developments in the Near East and particularly in Africa, progress has clearly been made in Southeast Asia and Latin America. This is the consequence of the so-called *green revolution*, with improved yields resulting primarily from successes in the breeding of wheat, rice, and maize. The introduction of more productive varieties better adapted to local conditions has led within a few years to increases in yields that had remained unchanged for centuries; results in some cases were sensational. Initial setbacks showed that the full realization of the genetic potential of the new varieties required new techniques, often including fertilization and flanking plant protection. These methods have been successful in many countries and led to solutions of acute problems of malnutrition. The examples of India, Mexico, and Thailand are given in Table 1 [4].

Clearly, it is difficult to keep agricultural production ahead of a sharply rising population. Nevertheless, the situation can be improved, especially in the developing countries, by modernization of agriculture, principally the choice of variety (plant breeding), fertilization, and plant protection [12].

3. Crop Protection in Modern Agriculture

Crop protection includes all measures of crop maintenance, from sowing to harvest and even to processing and consumption. It extends to all kinds of damage, whether abiotic or biotic. As in human and animal medicine, prevention and hygiene are crucial. Early protective measures are the province of husbandry, which merges by easy stages with plant protection. For example, tillage and the selection of crops for rotation also serve to control weeds, nematodes, and other pests. The choice of varieties and plant nutrition can have considerable influence on the physical condition of crops. Crop protection is not generally thought to include seed purification to prevent weeds, but does include seed dressing for the prevention of fungal infections, as well as quarantine measures against pests or pathogenic organisms.

Plant protection ordinarily applies to entire crops rather than individual plants and is therefore analogous to population medicine. This is particularly true of biological control (see Section 5.3), whereas physical and chemical measures may sometimes be applied to individual plants as well as whole stands of crops.

Crop protection measures are generally classified according to causes of damage or the harmful organisms. Chemical agents are characterized as insecticides, acaricides (against mites = acari), fungicides, herbicides (against weeds and wild grasses), nematocides, rodenticides, and others. Chemical measures have predominant importance for the control of biotic damage. In 1985, world consumption of crop protection products was estimated at $\$ 13\,788 \times 10^6$ (users' prices) of which $\$ 4268 \times 10^6$ represented insecticides, $\$ 2537 \times 10^6$ fungicides, $\$ 6331 \times 10^6$ herbicides, and $\$ 642 \times 10^6$ all others [13]. Therefore, insecticides constitute 31 %, fungicides 18 %, herbicides 46 %, and other products 5 % of consumption. This distribution is subject to regional variation according to climate, crops planted, and the stage of agricultural development. In general, herbicides dominate in the industrialized countries with high labor costs. In 1985 in the United States, the proportion of herbicide consumption was 69 %, insecticides 23 %, and fungicides 8 %,

Table 1. Food production in India, Mexico, and Thailand [4]

	India	Mexico	Thailand
Cereal production, 10^6 t			
1974 – 76	119	16	17
1984	169	26	24
Increase of per capita cereal production *, %	19	29	11
Increase of food production *, %	38	34	25
Increase of per capita food production *, %	14	4	15

* Based on 1974 – 1976 data

whereas in western Europe, the share of herbicides accounted for 47 %, insecticides 17 %, and fungicides 36 %. In 1985 the United States represented 32 % of the world market in crop protection products, Western Europe 22 %, and Eastern Asia including Japan 19 %.

The world pesticide market is shown in Table 2, sales value and distribution of uses in Table 3, and use patterns in Table 4.

Fruits, Vegetables, and Horticulture. Fungicides and insecticides have the greatest importance in the intensively grown crops of fruit, citrus, grapes, vegetables, and garden plants, but the use of herbicides is limited in that case. In fruit cultivation, ground cover is often maintained to conserve soil moisture, with mulching by regular cutting. In growing vegetables and ornamental plants with their numerous varieties weeds are controlled mechanically to avoid problems of varietal compatibility with herbicides. High-quality produce must be free of damage. Although these foodstuffs spoil easily, relatively high returns can be achieved per unit area with special crops allowing a high investment in crop protection. Moreover, in such permanent crops as fruit, citrus, and grapes, characteristic complexes of pathogenic organisms have become established, including scab, powdery and downy mildew, and other fungus diseases. The insect pests include several species of moths (*Tortricidae*), weevils (*Curculionidae*), and others. The soft epidermis, considered desirable in the edible parts of many vegetables, reduces resistance to disease.

Cereals. A completely different pattern is shown with crops grown on a large scale. In maize and the other cereals (wheat, barley, rye, oats), weed control has become largely a domain of agrochemistry. With increasing costs of mechanical weed control, the application of herbicides has become standard practice. Selective products that control weeds in cereals without harming the crop have been developed. In maize, herbicides account for 71 % of all crop protection measures. Insecticides are, however, still important in the control of soil pests, which in many areas result partly from the cultivation of maize without crop rotation. With the traditional cereals, in which chemical weed control figures prominently, insects are of minor significance. In certain regions it may be necessary to control cereal bugs (*Eurygaster* sp.) and occasionally locusts.

In many countries, particularly in Europe, seed dressing is accepted agricultural practice and has almost eliminated many cereal diseases which had devastating effects in earlier times. Smut and bunt diseases have been suppressed. Other cereal diseases have gained in significance with the intensification of crop rotation and an increase in the density of planting. Most important among these are rusts, mildew, and some *Helminthosporium* and *Septoria* species that have been controlled with seed dressings and leaf sprays. Overall, diseases have become more prominent.

Rice. Rice represents special problems arising from farming conditions and climate. It is the classic example of single-crop farming. For the most part, it is cultivated on the same acreage over long periods of time without interruption through crop rotation. In many areas, rice cultivation offers the ecological advantages of regulation of water economy and prevention of soil erosion by terracing. As in every case of single-

crop farming, however, rice growing has favored specific pathogenic organisms adapted to the wet and warm irrigation environment. Among the harmful insects are stem borers, plant hoppers, aphids, and many beetle species.

Diseases and weeds also occur. Therefore rice cultivation employs all three classes of crop protective agents, insecticidal, fungicidal, and herbicidal, as is the case with hardly any other crop except peanuts. The rice farming acreage of the earth, at 145×10^6 ha, constitutes 10 % of the arable land area in the world.

Soybeans. Soybeans represent a typical cash crop. Herbicides account for 90 % of the crop protection cost. Large-area cultivation of soybeans would be unmanageable by mechanical weed control.

Cotton. During the entire history of cotton cultivation, insect attack has been a limiting factor [5]. The development of synthetic organic insecticides, chiefly phosphoric esters, has assured the economic viability of this crop in many climatically favorable areas [14].

Although weed control accounts for 22 % of crop protection costs, insecticides account for 76 % and cotton remains the typical insecticide-based crop. All green parts of the plant constitute ideal insect fodder.

Sugar Beet. Sugar beet cultivation is an instructive example of the almost fully mechanized management of an agricultural crop species [2]. The sugar beet yield in the developed countries was raised from an average of 35.5 t/ha in 1965 to about 50 t/ha in 1985. This enormous increase was accomplished with a drastic reduction in labor costs. In 1950, 130 h/ha were still required for tending beet; in 1973 this had been reduced to 30 h, and by 1985 to only 22 h [15].

For several reasons the European sugar beet cultivation faced a serious crisis in the 1950s. These problems have been solved by a succession of innovations. The result is a highly mechanized beet cultivation, less manual labor, higher yields, and more efficiency on acreage controlled by the farmer [16–18].

Following the development of herbicides that selectively eliminate most weeds without harming the beet crop, it turned out that the importance of hoeing had been overestimated in many cases. As with other crops, it eliminates weeds and accomplishes little more [19].

The elimination of manual weed control resulted in a labor saving of 30 – 40 %. However, the separation of beet seedlings continued to require a high degree of manual labor. Ecologically it began to be evident that polyphagous pests, which had formerly been distributed among weeds and crops, now concentrated on the host beets in the fields. This applies particularly to soil pests such as wireworms and cutworms but also to leaf and shoot pests such as pygmy beetles, weevils, diptera, springtails, and aphids. Without doubt, dense vegetation plays a part in limiting pest dispersion.

Hoeing was no longer economical for the separation of seedlings which had to be reduced from ca. 1 million to 70 000 – 80 000 beet plants per hectare. Therefore, plant breeders developed monogermous seeds first by mechanical and later by genetic methods. Consequently, only one seedling developed from each individual grain. Since it had become possible to equalize the number of seed with the final count of beet, mechanical or manual hoeing was no longer necessary. The beet field had therefore become a "blank slate," i.e., during the entire vegetation period, with perfect management, only the beet plants to be harvested remained.

The result, however, was the aggravation of some pest problems. When the number of beets planted correspond to the final count, the failure of each individual plant means an economic loss. The economic threshold is therefore much lower. The beet is the only plant remaining in the entire area as a host for phytophagous insects, and species that formerly had little significance have developed into serious pests.

The resulting problems have been solved partly by coating the seed with insecticides and partly by the application of insecticides to the emerging plants.

4. Economic Threshold and Prognosis

Control measures are necessary when damage is expected to exceed the *economic threshold*, understood as the degree of damage at which control costs are covered by the expected increase

in yield [20]. If control costs are higher than the expected profit, the damage is tolerated for economic and ecological reasons.

Table 5. Critical infestations

Pathogenic organism	Host	Conditions
European corn borer (*Ostrinia nubilalis*)	maize	4 – 8 eggs per 100 plants
Wire worms (*Elateridae*)	maize	1 wireworm per m^2 of soil
Foot rot in cereals (*Pseudocercosporella herpotrichoides*)	wheat	20 % of plants with brownish discoloration at stalk base at onset of sprouting
Colorado potato beetle (*Leptinotarsa decemlineata*)	potatoes	15 larvae per plant
Cabbage gall midge (*Dasyneura brassicae*)	rape	1 midge per plant
Summer fruit tortrix moth (*Adoxophyes orana*)	stone fruit	preflowering, 7 caterpillars per blossom cluster; postflowering, 1 – 3 caterpillars per 100 fruit
Wind-grass (silky bent grass, *Apera spica-venti*)	cereals	10 – 20 plants per m^2
Slender foxtail (black grass, *Alopecurus myosuroides*)	cereals	20 – 30 plants per m^2
Cleavers (*Galium aparine*)	cereals	0.5 plants per m^2

The economic threshold is determined by epidemiological and economic factors. The population density of pathogenic organisms depends on the propagation potential, weather conditions, resistance of the host plants, parasite infestation, soil condition, dispersion of infestation, and other factors. The economic components of this threshold are determined by the control costs, farm prices, yields expected, and the costs which have already been met. Because of the variability of these factors, the economic threshold fluctuates within a wide range. Some influences, such as weather, are notably unpredictable. A more uncertain prognosis requires a wider economic safety margin [21].

As shown in Figure 1, a regular epidemiological development often simplifies the prognosis [20], [22], [23]. In example A, the population density does not normally reach the economic threshold, and savings can be realized in control costs. In example B the pest multiplies under favorable conditions and, uncontrolled, would exceed the economic threshold. The most difficult decision is shown in example C, where the average population density of the pest is just below the economic threshold. In this case control measures became unnecessary because the pest population is reduced by parasites and predatory insects. In example D, the pest population is consistently above the economic threshold, and repeated control measures are indispensable. The decisions of the experienced farmer as to the use of control measures are based on threshold data and on careful observation of the situation under field conditions. Critical infestation figures are given in Table 5 [24].

In the attempt to improve the accuracy of prognosis, procedures have been worked out for apple scab (*Venturia inaequalis*), based on the ability of spores to germinate as a function of temperature and moisture (Fig. 2).

Automatic equipment for recording leaf moisture establishes a data base for apple scab prophylaxis. The prognosis of attack may be based on the number of insects caught in traps (light traps, pheromone traps, and mechanical traps).

Pathogenic organisms in a new area constitute a special case, depending on climatic conditions and on the presence of natural enemies and of suitable hosts. A prognosis requires the help of system analysis.

5. Methods of Crop Protection

5.1. Physical and Mechanical Methods

Mechanical and physical techniques are among the oldest methods of crop protection. Tillage measures such as hoeing, harrowing, and rolling of the soil, prepare the seed bed and help to control weeds. Terrestrial animals are excluded by fences, ditches, and traps. In Central Europe, for example, fencing is required to prevent deer from damaging forest plantations. Ditches protect conifers against pine weevils, cereals against cereal carabides or the broad-nosed weevil (*Otiorrhynchus*), and beets against root weevil (*Bothynoderes*). Mechanical traps are used against such insects as mole crickets (*Gryllotalpa* sp.) and also against mammals such as field mice and the moles (*Talpa europaea*). In some regions, field mice are controlled by temporary flooding, which has also been applied against grubs and other soil pests. Tangle glue protects fruit trees against the nonflying female

Figure 1. Relation between epidemiological type, economic threshold, and need of control [20], [22], [23]
A) No economic damage, e.g., rice leaf-miner fly (*Agromyza nigrella*)
B) Occasional economic damage, e.g., beet fly (*Pegomyia hyoscyami*)
C) Frequent economic damage, e.g., coddling moth (*Cydia pomonella*)
D) Continuous economic damage, e.g., plant lice as vectors in potato breeding
—— General equilibrium of population
– – – – – Control threshold
· · · · · · · Economic threshold
↓ Control required

of the common winter moth (*Cheimatobia brumata*).

Mechanical measures have even been tried to inhibit the propagation of fungus diseases. A long-term effort has been made to control stem rust in cereals (*Puccinia graminis*) by carefully rooting out the European barberry (*Berberis vulgaris*), the intermediate host on which the aecidia of the fungus develop. More recently the elimination of infected cotoneaster plants has given hope of delaying the introduction of fire blight caused by bacteria (*Erwinia amylovora*) on Rosaceae, including kernel and stone fruit. The trimming of the branches of fruit trees controls fructification and eliminates primary infections such as apple mildew (*Podosphaera leucotricha*).

Among thermal procedures, soil steaming is effective against soil pests, particularly in greenhouses. Cereal smut diseases (*Ustilago* sp.) can be controlled by treating the seed with hot water. The outbreak of some virus diseases can be delayed by heat. Stubble left after harvest is burned to reduce the chances of infestation, but with ecological side effects that may be serious. In some areas it is forbidden by law to burn stubble or weeds.

Crop protection includes refrigeration, e.g., the cold storage of fruit. This delays, but rarely prevents the development of pathogenic agents.

5.2. Chemical Methods

Chemical procedures play a dominant role in crop protection. The reason include their convenient adaptability to farming operations and the wide range of agents available for dealing with specific problems in accordance with legal regulations. In addition, it is fairly easy to calculate risk : utility ratios.

5.2.1. Goals

The goals of optimizing farming methods include (1) increase in yields, (2) improvement of the cost : profit ratio, and (3) accommodation to market conditions, or (4) advances in ecology. Chemical crop protection can make substantial contributions to all these areas [25].

When these goals conflict, it becomes necessary to set priorities and possibly to make compromises, always with a view to long-term cultivation efficiency.

Figure 2. Chances of infection by apple scab (*Venturia inaequalis*) in relation to moisture and temperature [24]

5.2.2. Requirements

The requirements that modern crop protection products must meet include selective action, low persistence, high efficacy, and no intervention with natural equilibrium.

Selective Action. The selectivity requirement for herbicides on the one hand, and insecticides and fungicides on the other, are fundamentally different: a selective herbicide should have the greatest possible effect on all plant species in the field, with the exception of the crop itself. Selective insecticides or fungicides, on the other hand, should be effective against only one species, the target organism, with no effect on any other species in the ecosystem. These requirements encounter the following difficulties:

1) Insecticide compounds may be *monotoxic*, i.e., acting on a specific species, *oligotoxic,* i.e., group-specific, or *polytoxic,* i.e., with a broad spectrum of effect. For ecological reasons higher specificity is generally preferred since a minimal disturbance of the ecosystem, including the beneficial fauna, is expected of monotoxic action. Such specific effects occasionally lead to shifts in the dominance of species because competitors of the eliminated species have utilized the new "ecological niche," thereby taking the place of the target organism.
   An example is the Central European viniculture, where the grape berry moth species *Clysia ambiguella* and *Polychrosis botrana* were first controlled successfully. However, then a species of beetle, the hazal leaf roller, *Bytiscus* sp., became a significant vinicultural pest.
   Herbicides, may also lead to a shift in the dominance of the species within weed societies. The specific action of the growth-hormone herbicides derived from β-indolylacetic acid on dicotyledonous weeds has, in many cases, led to the multiplication of monocotyledonous grasses in cereals, e.g., wind grass (*Apera spica-venti*) or slender foxtail (*Alopecurus myosuroides*).
   Resistance can develop to crop protection products with a specific action. Within the genetic variation of a population chemical intervention selects the resistant individuals, and facilitate their propagation by eliminating the rest of the species; resistance thus builds up. A narrow spectrum of action promotes such developments because the restriction of the effect to specific biochemical processes means that minor deviations from these models cause a loss of efficacy. The great genetic variability of the fungi causing plant diseases imparts considerable significance to this phenomenon.
2) Products with a specific action tend to be more expensive than those with a broad spectrum of effect. For such products research costs have risen disproportionately and the

probability of discovering new pesticides drops with each additional requirement [26]. On the other hand, thorough testing is necessary for the biological validation of selective effects. In addition, the market for products with specific action is naturally smaller than for broad spectrum products.

3) The great number of products available, each with a narrow spectrum of effect, requires careful diagnosis and selection. The demand for higher specificity has resulted in a broad assortment of specialized products.

Low Persistence. The ideal behavior for a crop protection compound is to persist in the environment long enough to accomplish its purpose and then to be degraded rapidly to naturally occurring substances. Evidently, it is not always possible to satisfy both requirements. If the fungal spores are dispersed over a long time or the hatching of insects is delayed, repeated treatment may be necessary. This can be avoided with compounds of higher persistence.

High Efficacy. A modern crop protection product should be applied at the lowest possible dosage of active ingredient per unit of area,that is at high efficacy. This requirement is largely met by new products which are applied in the following dosages [27]:

Active ingredient	*Dosage, g/ha*
Insecticide	
lead arsenate	2000 – 5000
DDT	1000 – 2000
diflubenzuron	125 – 250
deltamethrin	10 – 25
Fungicide	
sulfur	2000 – 5000
dithiocarbamate	1500 – 2000
metalaxyl	125 – 200
triadimefon	50 – 125
Herbicide	
sodium arsenite	1500 – 3000
metribuzin	250 – 500
chlorsulfuron	15 – 20

In all three areas of application, dosages of less than 100 g/ha have been reached, sometimes with a more than 100-fold reduction of dosages of older compounds. Ecological risk is reduced correspondingly. The uniform distribution of such small quantities requires careful formulation, whether as wettable powder, emulsifiable concentrate, granule, or dust. Products of such high efficacy also require careful dosage and even application.

Interference with Natural Equilibrium. The naturel equilibrium should not be disturbed by crop protection, although agriculture itself constitutes intervention into natural processes (see Section 1.1). In view of the complex character of ecosystems, the effects of individual compounds are difficult to assess [28].

5.2.3. Effects on Farming

Crop protection contributes to farming success by safeguarding yields threatened by natural causes. The methods employed range from soil preparation to the protection of the harvest itself and extend to transport and storage. Most importantly, these methods must meet the criterion of cost efficiency.

Soil. Soil treatment protects seed, seedlings, and developing root systems from animal pests, fungi, other microorganisms, and weeds. Active compounds tend to degrade rapidly in soil, although photochemical decomposition is slow. The apparently conflicting goals of persistence and rapid deactivation have been achieved by the development of slow-release granules, from which the active ingredient is gradually liberated by the action of soil moisture. After release, degradation is rapid. Such granules are used against soil insects in maize, beets, grapes, and vegetables.

Soil fungicides are not normally used with crops planted on a large scale, but are restricted to special crops such as ornamentals or hops. Increasing problems with nematodes have made the use of nematocides necessary, especially in crops managed without sufficient rotation. Soil herbicides are used in all developed countries.

Farming Studies. Unique long-term studies on the effect of crop protection on yields have been conducted on two experimental farms in the Rhineland with favorable growth conditions and a normal weed flora (see Tables 6 and 7).

At Höfchen the soil is loam or loess loam, at Laacherhof brown and similar earth. The weed flora in untreated areas is normal on both farms, and the yield reaction to weed control is not excessive. The yield increases in untreated soil,

calculated from the mean yield surplus of up to 16 years of investigation, may be considered largely representative. For the traditional cereals (Table 6), they show a yield increase from 9 to 17 % in the winter varieties; for all winter cereal species taken together, the result is a mean increase in yield of 12 – 13 % resulting solely from the use of herbicides applied mostly before emergency as in normal practice. There are no basic differences between these two farm sites.

In the summer cereals, with shorter growth periods, the yield effects are less clear, averaging 6 %.

In maize, the 16-year comparison shows that yield more than doubled with herbicides. As hoeing is indispensable if herbicides are not used, the comparison includes mechanical weed control, with results similar to other summer cereals.

The yield per hectare for winter wheat in Höfchen was 5.1 t, increased by treatment to 5.6 t. If a producer price of $ 160/t is assumed,

Number of trials	Efficacy, %	Yield increase, t/ha	Yield increase, %
22	1 – 20	0.72	22
58	21 – 40	0.73	22
118	41 – 60	0.89	27
237	61 – 80	0.92	28
123	81 – 90	1.22	37
285	91 – 100	1.20	36
Total 843		Mean 1.03	31

the gross income is increased by $ 90/ha. If single preemergence treatment costs are $ 48 – 60, net income is increased by $ 28 – 40/ha.

The actual gain is, however, higher because weeds in cereals retain moisture and increase drying costs. They also create mechanical difficulties, particularly with the combine harvester if the weeds mat in the cutter bar. The threshing operation also requires thoroughly dried and ripened kernels.

In the case of tubers, seeds, vegetables, and berries, yield comparison between herbicide-treated and -untreated crops is not realistic because these crops cannot be grown economically without mechanical weed control. In Table 7 chemical and mechanical weed control are compared. The yield increases caused by herbicides are of economic importance because of the higher monetary value of most of these crops, and the higher labor costs of mechanical procedures.

The advantage of chemical methods is largely due to the absence of root damage caused by mechanical procedures, and possibly to loss of moisture caused by breaking up the soil.

Comparable trials have not been conducted on insect control, although an evaluation of insecticides in *rice* cultivation has been carried out in Asia and Colombia (see Table 8).

The yield also increases with the efficacy of the insecticide used; however, this effect levels off at about 80 % efficacy (Table 9).

Insect control improves not only yield but also crop quality and storage stability. Freedom from infestation increases the value of the crop.

Similar results are obtained by treating diseases in *wheat* with fungicides [9]. On the average, the yield in the treated plots was 5.83 t/ha compared to 5.29 t/ha in untreated plots, an increase of 0.54 t/ha or 9.3 %. The results of treating mildew in wheat are given in Table 10 [9].

As with rice insect pests, the yield is lower at high infestation even in treated plots. When the efficacy of the fungicide increases, the yield is also increase (Table 11).

Highest efficacies (91 – 100 %) produce a mean yield increase of 0.76 t/ha. In contrast to insect control, there is a considerable yield difference (almost 0.2 t/ha) between the efficacies of 81 – 90 % and those of 91 – 100 %.

As with other crop protection measures, the increased yield is accompanied by improved quality.

Sugar beet yields, for example, are higher in all respects with chemical than with mechanical control (see Table 12).

In addition to yields, chemical crop protection improves crop production systems. To

Table 10. Yield increase by mildew control in wheat* [9]

	Degree of infestation		
	Low	Medium	High
Yield, t/ha			
Untreated	5.61	5.69	4.82
Treated	6.02	6.18	5.54
Increase	0.41	0.49	0.72
Increase, %	7	9	15

* 1914 trials.

this end, the increasing significance of no- or minimum-tillage systems offers an interesting example [1]:

In many parts of the world, traditional tillage systems are being replaced by mechanical and chemical innovations. The steel moldboard plow, introduced in 1830, is stilltoday the basic tool for preparing the seedbed. However, it is energy-intensive and, under certain conditions, suffers from serious disadvantages. It exposes the soil to wind and water erosion and may disrupt the soil – water balance. Plowing can lead to hard plow pans and preserve weed seeds for later germination.

Table 11. Relation between yield increase and efficacy of fungicide in wheat cultivation

Efficacy, %	Yield increase, t/ha
1 – 20	0.3
21 – 40	0.48
41 – 60	0.5
61 – 80	0.53
81 – 90	0.56
91 – 100	0.76

In no-tillage systems, also referred to as zero-tillage, or in chemical tillage systems, crops are planted in unprepared soil by opening a narrow trench just wide and deep enough to provide seed coverage. There is no other soil cultivation. Weeds are controlled by herbicides, and soil pests by insecticides and nematocides. The advantages include better soil moisture retention and reduction of rainfall run-off, water and wind erosion, soil damage by machinery, energy consumption, and production costs.

No-tillage with the application of herbicides, insecticides, and nematocides is a valuable option for regions with serious problems, such as drought, erosion, unstable soils, or unfavorable climatic conditions.

Reduction of Losses. A long-term study at the experimental farm of Laacherhof, Federal Republic of Germany, shows that inadequate crop protection measures reduce apple yields (see Table 13). Similar results have been obtained with other crops [1].

5.3. Biological Methods

Biological pest control is understood as "the use of living organisms (through human intervention) to limit the populations of certain harmful animals or plants" [32]. *Biotechnical procedures* "utilize natural reactions of pests to certain physical or chemical stimuli which achieve an objective other than that associated with their natural significance for the organism"

Table 12. Yield increase of sugar beet with herbicidal over mechanical control* [30]

None	13.8	4.6	57	19

[32]. Examples include the use of repellents and attractants; pheromones; growth, molting, and development hormones; and optical, acustic, olfactory, and tactile stimuli. The term biological crop protection is often understood to include biotechnical procedures (→ Biological Control).

Weed and Fungus Control. In Chapter 3, it was mentioned that, for chemical crop protection products, 46 % of the world market represents herbicides and 18 % fungicides. In the developed countries, two-thirds of all crop protection expenditures are for herbicides. Attempts to control weeds biologically have employed monophages or oligophages, i.e., insects adapted to certain host plants; phytopathogenic fungi have also been employed. The following problems have arisen:

In actual farming, weed control almost always applies to weed societies rather than individual species, and extends to all species competing with the crop.

In principle, specific competitors can be found to control individual weed species, but the control of weed societies requires competitors for each species; otherwise, ecological niches would open up, to be occupied by the remaining weed species. Polyphagous antagonists cannot be used because they are pronee to attack the crop also.

At present, no practical procedures are available for the biological control of pathogenic fungi; antagonists are being investigated, which may act via metabolic products or competitive behavior. Thus far, insect control remains the principal area for the application of biological procedures.

Insect Control. Biological control procedures have not been established for large-scale cash crops [1], [33]. The annual harvesting of cereals, soybeans, beets, and potatoes has hindered the establishment of a balance between pest and competitor, and in crop rotation has changed biozoenotic conditions fundamentally. Almost half of all successful projects were conducted on islands where dispersion was restricted. Control of pests imported into new areas has been highly successful. In addition, biological procedures are favored whenever the economic threshold is high, e.g., in a forest.

A good example of biological control of insects is provided by parasites and predators against a pest infesting a permanent island crop with a high economic threshold. In the absence of other pests, chemical measures are unnecessary.

Microbiological procedures have also been used for pest control. Uncontrolled propagation of microorganisms with possible unforeseeable ecological effects must be avoided.

5.4. Cultivation

Cultivation techniques can strongly influence the susceptibility ofcrops to infestation. These methods are based on the choice of crop and variety, a sound crop rotation scheme, and tillage intensity. This should give the optimum sowing schedule and technique and the best fertilizing and tending methods.

Choice of Site. Site conditions are determined by climate and soil; tillage under the best conditions is of prime importance. Plant breeding has developed varieties suited to areas beyond the original habitat and differing from it with respect to temperature, precipitation, hours of daylight, and other factors. By avoiding unfavorable site conditions, e.g., those prone to certain infestations, the farmer can improve the crop and reduce the probability of damage. This is important in the propagation of seed or plants. Seed potatoes, for example, are propagated in so-called healthy locations, in which climate does not permit the multiplication of aphids, which are vectors of virus diseases.

Crop Rotation. Crop rotation is among the oldest methods for maintaining soil fertility and preventing damage. In Central Europe, the three-field operation had already come into existence by the 8th century. In this system, the cereals cultivation, if possible with two different species, was followed by a fallow year which regenerated the soils and restrained the growth of weeds and pests. This system was maintained for thousand years; it was superseded only in the 18th and 19th centuries by the improved three-field economy [34], [35], in which the fallow was replaced by red clover. In addition, the introduction of potatoes and sugar beets in Central Europe permitted the inclusion of dicotyledons in the crop rotation practice. This represented considerable progress, with advantages that extended to weed control. Crop rotation usually included two-third cereals and one-third dicotyledons, i.e., clover, potatoes, and beets; 9 – 11 field rotations were practiced [34], [35]. Crop rotation of many individual components is, however, not practicable for economic reasons, but oversimplified crop rotation entails various risks.

Soil Treatment. Soil treatment and fertilization are closely related to the probability of damage. Certain nutritional deficiencies often predispose to infestation. On the other hand, an excess of nutrients, especially nitrogen, may favor other forms of infestation, such as aphids or cereal fungi.

Scheduling. The planting schedule can be so arranged as to avoid late frosts or other critical periods. In Scotland, late planting reduced the population of the cabbage root fly (*Phorbia brassicae*). After the first spring generation had laid its eggs, the initial infestation was depressed during the vegetation period. However, part of the growing season had to be sacrificed [36].

Mechanical Methods. Sowing depth and the seedbed quality influence germination and emergence of the crop; on the other hand, deep plowing and turning of the soil bury the weed seeds, which may preserve them in the ground until the next plowing.

The land surrounding the cultivated area may be developed. Hedges and borders influence local climatic conditions and provide a habitat to birds of prey, insect-eating songbirds, hedgehogs, and predatory and parasitic insects. On the other hand, vegetation may serve as an intermediate host for diseases and pests. The advantages usually tend to outweigh the disadvantages, especially where crop protection measures are employed.

5.5. New Methods

New tendencies in crop protection extend to biotechnology, modern methods of organic synthesis, electronic data processing, and integrated systems in farming [10], [37].

5.5.1. Biotechnology

Biotechnology can be utilized in microbiological, genetic, and diagnostic methods [38]. Both microorganisms and their products of metabolism can be used as pathogens or pathogen antagonists. Metabolism products obtained from microorganisms include antibiotics, such as blasticidin, which was developed against rice blast (*Pyricularia oryzae*). Kasugamycin, validamycin, and polyoxin are related. The use of antibiotics in crop protection has been restricted by the fear of creating resistance, which might even extend to human pathogens.

Antibiotics. A nucleotide antibiotic with an effect like that of an acaricide has been developed under the name niccomycin; high costs, however, have kept it off the market [39], [40]. On the other hand, avermectin, obtained from *Streptomyces avermitilis,* is an effective insecticide and acaricide in such low dosages that it has aroused great interest [38]. The herbicides bialaphos and phosphinotricin are derived from other *Streptomyces* phyla. These are all clearly defined biogenic substances, which can be produced synthetically or biologically, according to costs.

Microorganisms. Microorganisms are applied directly to control phytopathogenic fungi, animal pests, or weeds. Spore preparations are obtained from *Verticillium lecanii*, a fungus that affects aphids and white flies (*Aleurodinae*). The fungus *Trichoderma harzianum* has an antagonistic effect on the phytopathogenic fungus *Stereum purpureum* and is used for sealing

wounds in fruit trees. *Colletotrichum gloeosporiorides* f. sp. *aeschynomene* is used as a spore preparation in soybean and rice against the weed *Aeschynome virginica.* The action is highly specific and is usually supplemented by chemical herbicides [38].

Genetic Engineering. Genetic engineering may provide crop protection by increasing the pathogenicity or antagonistic action of a microorganism. More direct is the genetic alteration of the crop itself; in this case, the line between cultivation and crop protection may become difficult to draw. The important objectives here include the improvement of photosynthetic efficiency and nutrient assimilation and of resistance to drought, disease, and chemical agents. A special case is the creation of herbicide resistance through genetic engineering. Its goal is maximum selectivity and compatibility with crop species. This should reduce the amounts of herbicides used, if postemergence as well as preemergence application becomes possible.

An example of genetic engineering is the herbicide tolerance induced in rape. The utilization of rape as an oleaginous and protein plant was limited by the high content of erucic acids and glucosinolates. Traditional plant breeding created rape varieties free of erucic acids and glucosinolates. This, however, did not guarantee crops of a pure variety because when rape seed is combined, many seeds are shed and remain in the field, retaining viability for 6 – 8 years. Later cultivation mixes the old varieties with the new ones which are free of erucic acids and glucosinolates. This could be prevented if the new varieties were tolerant of a herbicide that destroyed seeds of the old variety in the soil. The "weed rape" could then be eliminated selectively. This practice has reached an advanced stage of development.

Diagnosis. Biotechnology can also be applied to diagnosis, especially in the early stage of a disease, by the use of so-called DNA-probes. A mixture of the DNA of the fungus and of the host plant is prepared by dissolving the DNA in individual filaments, e.g., from plants infested by the fungus. The DNA segments of the fungus, which have previously been cloned in bacteria are added to this mixture. These segments seek out the complementary DNA segments of the fungus. The result is a hybridization which shows that the host plant has been infected. Such "diagnosis kits" are already used in medicine and could advance the early recognition of plant diseases [38].

5.5.2. Research Methods

Chemicals for crop protection are developed by empirical research, research by analogy, and research based an structure – activity relations. The traditional empirical method employs more or less random screening of a large number of compounds to find those that combine efficacy with minimal side effects. Although the statistical chances of success are small (12 000 : 1) the probability of discovering totally new classes of active substances is relatively high.

Research by analogy proceeds from classes of compounds with known biological activity, in the hope of improving the properties by structural changes. This strategy offers a high probability of gradual progress but a smaller probability of scoring a breakthrough. Nevertheless, such important properties as systemic efficacy have been detected by analogy research.

With increasing knowledge of biochemistry and molecular biology research into constitutional effects is receiving more emphasis. The "lock – key principle" is used to bring the active substance to the specific site; compounds are "tailor-made" to accomplish calculated physiological effects [41].

5.5.3. New Indications

New farming ventures will require new functions and new approaches in crop protection. The growing of new types of crops in arid regions or in regions with high salt concentrations will create new problems of crop protection. The same applies to the perspective of "energy farming."

The development of new or modified crops for this purpose, in regions not traditionally accessible to agriculture, will produce new kinds of problems.

5.5.4. Integrated Systems

Crop protection problems cannot be viewed in isolation. The range of possibilities, from mon-

itoring and prognosis to physical, mechanical, chemical, biological, tillage, and biotechnological methods, suggests looking for practical combinations and their optimization. *Integrated crop protection* is defined as "a system in which all justifiable economic, ecological, and toxicological methods, combined with natural factors of limitation, are employed to keep infestations of injurious organisms below the economic threshold. Special emphasis is given to the exploitation of the natural factors of limitation."

Integrated crop production is defined as "a system in which all cultivation methods are coordinated with the soil and the climatic conditions of the site. The goal is a high yield of good quality over a period of many years, with full consideration of ecological and economic effects" [35]. Such methods create an increasing need for products to control pests, diseases, or weeds from the time of sowing until harvest [10]. The development of integrated systems is facilitated by the use of electronic data processing.

6. Safety Aspects

Undesirable side effects of crop protection agents must be kept to a minimum to guarantee safety for the user, the consumer of the agricultural products, and the environment. Safety precautions in the production, transport, and storage of these products are equally necessary.

6.1. Safety for the User

The chance of exposure to crop protection products is greatest during application, and questions of acute and chronic toxicity are of particular concern to the user.

Toxicity data are required by all countries that impose legal restrictions on crop protection, i.e., over 90 % of all the countries in the world. These requirements include regular medical examinations of workers in regular contact with these products. Short-term, chronic, and cumulative effects must be determined as well as carcinogenic, teratogenic, and mutagenic effects.

The toxicological data are reflected in the recommendations for use that accompany the commercial product, and that include provisions forbidding use while eating, drinking, or smoking, or applying the product in a high wind.

Breathing masks and protective clothing are recommended, and adherence to proper dosages and disposal procedures are required, as well as thorough washing after use.

Safety instructions extend to the labelling and closure of the package, and first aid instructions in cases of poisoning. The equipment must be in good condition and provide precise metering of dosages; performance must be checked regularly.

6.2. Safety for the Consumer

Consumer safety requires the absence of residues of crop protection products that might be injurious to health. This rule must be strictly observed with food.

Physical loss and chemical decomposition decrease the concentration of the pesticide more or less rapidly, depending on its stability and the conditions. The concentration is then measured against toxicological standards established by feeding experiments on at least two animal species. The upper limit of tolerance, defined as the amount that creates no pathological changes, is expressed in mg/kg of animal weight and called the *no effect level* (NEL). In extending the results of animal experiments to humans, an additional safety margin is employed according to international custom, usually by establishing one percent of the lowest NEL. The value established by this method is the *acceptable daily intake* (ADI), expressed in mg/kg:

$$\frac{\text{NEL}}{\text{safety margin}} = \text{ADI}$$

This is the base value for the determination of tolerances or maximum limits. These are the highest acceptable residue concentrations of crop protection products established by legislation. In order to establish tolerance, the ADI value is multiplied by the body weight (BW). However, to comply with the contribution of individual foodstuff to the total diet, the product is then divided by a nutritional factor to obtain the toxicologically *permissible level:*

$$\frac{\text{ADI} \times \text{BW}}{\text{nutritional factor}} = \text{permissible level}$$

Accordingly, staple food contributes to the permissible level to a larger extent than specialty

foods. The permissible level assumes a fixed, life-long intake of the residue. For the legislator, this constitutes the upper limit for the establishment of tolerance. The maintenance of the tolerance values in farming practice is still an unsolved problem, because not every lot of produce can be analyzed for residues.

From the known rate of degradation a waiting period or period of nonavailability is established, during which the residue concentration falls below the permissible level. In practice, a prolongation of this waiting period is established if the period between the last application of the pesticide and the harvest can be chosen to be longer than the period of nonavailability. Extending the waiting period then offers additional safety. At the time of harvest, the residue value may have fallen still further below the permissible level. The tolerance values established accordingly are designated as tolerances of *good agricultural practice.* In the Federal Republic of Germany, for example, they constitute the basis for the tolerances established in the "Höchstmengenverordnung Pflanzenschutz" (crop protection regulation governing maximum residue limits).

Differences in safety requirements in different countries have complicated international trade in foodstuffs. Furthermore, crop protection practices and legislation differ from country to country. For example, the growing of fruit in warmer climates requires more insecticides whereas cooler and wetter climates require more fungicide.

In many countries official agencies carry out so-called market basket analyses. A typical selection of foodstuffs is bought, representing the weekly purchases of an average family, and subjected to residue analysis. Thousands of such analyses have given surprisingly similar results: About 80 % of the samples were found free of residues, about 18 % showed residues within legal tolerances, and in 1 – 2 %, tolerances had been exceeded [42]. Considering that the established tolerance values represent legal values rather than toxicological threshold values, these results must be seen as remarkably favorable. They speak well for the farmers who use crop protection products [42].

Furthermore, the situation has been improving from year to year, because more and more highly persistent products are being removed from the market. Examples of test results are given in Table 14.

Residues, when found, are usually far below the tolerance value. For example, in the Federal Republic of Germany from 1977 to 1980, the residues of organic chlorocompounds in milk were 0.2 – 5.0 % of the permissible ADI value [21].

7. Legal Aspects

The varied aspects of crop protection products (sale, handling, residues in foodstuffs and environment, consumer protection) are controlled in many countries by a system of legal regulations. The laws deal with chemicals (e.g., DDT), foodstuffs, toxic substances, and water conservation, as well as with the protection of crops and environment and methods of proper testing of pesticides [43–45].

Legislation is composed of the following elements: protection of crops; protection of the user, the consumer of foodstuffs, and the environment; and registration of crop protection products, i.e., automatic prohibition of all products not registered. Registration usually requires data on metabolism in plants and animals, on leaching action in the soil, and on toxicity to two mammal species, two bird species, and water and soil organisms.

These principles constiute the basis of the Japanese *Agricultural Chemicals Regulation Law* of 1948, as amended by several laws between 1949 and 1984 [46]. The following provision is made:

"The purpose of this law is to conduce to stabilization of agricultural production; protection for health of people; to contribute to environmental conservation of the life of the people, intended for normalization of the quality of agricultural chemicals with insurance of their safe and correct use by establishing a registration system and exercising control over sale and the use concerning agricultural chemicals." (Article 1). "Any manufacturer or importer of agricultural chemicals shall not sell the same unless he has registration granted from the Minister of Agriculture, Forestry, and Fisheries, of each agricultural chemical which he has manufactured, processed, or imported." (Article 2, § 1)

Parallel U.S. regulations are found in *The Federal Insecticide, Fungicide and Rodenticide*

Table 14. Residues in fruits and vegetables in the Federal Republic of Germany [21]

Act (FIFRA), of 21 Oct. 1972, as amended in 1975 and 1978 [47]:

"Requirement: Except as otherwise provided by this Act, no person in any State may distribute, sell, offer for sale, hold for sale, ship, deliver for shipment, or receive and (having so received) deliver or offer to deliver, to any person any pesticide which is not registered with the administrator."

The German *Crop Protection Law of 10 May 1968* was modified by the *Third Bill for the Amendment to the Crop Protection Statute* [48], [49]. Its purpose is:

1) "to protect crops from injurious organisms and diseases (crop protection),
2) to protect harvests against injurious organisms (protection of stores),
3) to influence the life processes of plants through the use of substances which are not intended for the nutrition of plants, and
4) to prevent harm which might occur in the use of crop treatment products or other measures of crop protection or protection of stores, particularly where this may involve the health of human beings and animals."

Other paragraphs govern mandatory registration. In the meantime, crop protection legislation has been brought up to date (1986), but this has not yet been promulgated. Essential portions of this amendment will become effective on 1 Jan. 1987, others on 1 Aug. 1988 [50]. A new aspect of this legislation is that crop protection measures must not endanger the "balance of nature." Components of this balance are defined as "soil, water, air, animal and plant species, as well as their systems of interaction." In addition, the principles of integrated crop protection as a component of good agricultural practice are embodied in law. The legislative action to be ex-pected will be of significance for the further development of crop protection.

Furthermore, it was stipulated that international agreements must be observed, in particular, the Code of Conduct adopted in November 1985 by the Food and Agricultural Organization (FAO) of the United Nations. This Code of Conduct has been developed for the guidance of developing countries with inadequate crop protection legislation [51]. It includes testing methods, development of products with high user safety, analysis of the residue effects, equalization of quality standards, packaging specifications, simple directions for use (possibly including pictograms), sales and advertising regulations, and observance of the guiding principles of WHO and FAO. In addition, cooperation between importing and exporting countries is mandated.

1. Crotonaldehyde

Crotonaldehyde or 2-butenal [*4170-30-3*] exists in two stereoisomeric forms: *cis*-crotonaldehyde [*15798-64-8*] and *trans*-crotonaldehyde [*123-73-9*]. Both isomers are contained in commercially available crotonaldehyde, in which the trans isomer predominates (> 95 %) due to its higher thermodynamic stability. Crotonaldehyde is a colorless liquid with strong lacrimatory properties and a pungent odor. Crotonaldehyde occurs naturally in many plants and plant products, e.g., french beans, rapeseed oil, and soybean oil.

1.1. Physical and Chemical Properties

Some physical properties of crotonaldehyde are summarized in the following [3], [4]: Crotonaldehyde is soluble in water and miscible with many organic solvents. Due to its double bond and the carbonyl group, crotonaldehyde is very reactive. Contamination with alkali or strong acids readily induces exothermic condensation reactions [1]. Crotonaldehyde dimerizes to dicrotonaldehyde (5,6-dihydro-2,6-dimethyl-2*H*-pyran-3-carboxaldehyde) when exposed to strong acids [2].

Boiling point	102.2 °C
Melting point	− 69 °C
Density (20 °C)	0.852 g/cm^3
Refractive index n_D^{20}	1.438
Heat of vaporization	515 J/g
Crotonaldehyde – water azeotrope	24.8 wt % H_2O
Azeotrope *bp*	84 °C
Solubility in water (20 °C)	150 g/L
Solubility of water in crotonaldehyde (20 °C)	9.5 g/100 g
Flash point	13 °C
Auto ignition temperature	155 °C
Explosion limits in air	
lower	2.1 vol %
upper	15.5 vol %

The most important classes of reactions involving crotonaldehyde are hydrogenation, reduction, oxidation, and addition reactions.

Reduction. Both the C – C double bond and the carbonyl group can be reduced. Most economically this can be achieved by catalytic hydrogenation, e.g., in the presence of nickel or copper catalysts [5]. Lower temperatures and pressures lead to selective hydrogenation of the olefinic moiety, which was formerly used to produce *n*-butyraldehyde [6]. Nowadays butyraldehyde is normally made by hydroformylation of propene. The hydrogenation of both the double bond and the carbonyl group leads to *n*-butanol [5], which is today usually produced by hydrogenation of *n*-butyraldehyde. Crotonaldehyde may also be catalytically hydrogenated selectively at the carbonyl group to give crotyl alcohol $CH_3CH{=}CHCH_2OH$ [7–9].

10.1002/14356007.a08_083

Oxidation of crotonaldehyde leads to crotonic acid (see Chap. 2).

Additions. The ease of addition of a large variety of molecules to the double bond makes crotonaldehyde an important chemical intermediate. For example, alcohols or thiols [10], [11] can be added to the olefinic double bond with a basic catalyst. This reaction is particularly important for the synthesis of 3-alkoxybutyraldehydes. The specialty solvents 3-Methoxybutanol [12], [13] and 3-methoxybutyl acetate can be synthesized by the addition of methanol to crotonaldehyde followed by consecutive hydrogenation and esterification of the intermediary 3-methoxybutyraldehyde. Crotonaldehyde acts as a dienophile in Diels – Alder reactions [14].

1.2. Production

The usual method to produce crotonaldehyde is the aldol reaction of acetaldehyde followed by dehydration of the acetaldol and distillation. Typically the product is about 99 % pure.

$$2\,CH_3CHO \longrightarrow CH_3CHOHCH_2CHO \longrightarrow (E)\text{-}CH_3CH{=}CHCHO + H_2O$$

The aldolization can be catalyzed by all types of basic catalysts, e.g., alkali metal or alkaline earth metal catalysts [15–18], ammonium salts [19], [20], zeolites [21–23], molecular sieves [24] and claylike materials [25]. Acetic acid, mineral acids, or acidic cation-exchange resins are used as catalysts for the dehydration of acetaldol [26], [27].

Major producers of crotonaldehyde are Celanese Chemicals, Daicel, Eastman Chemicals, and Sasol.

A flow diagram of a typical continuous crotonaldehyde production unit is depicted in Figure 1.

Acetaldehyde is aldolized in the water-cooled aldol reactor (a) with aqueous sodium hydroxide as catalyst. The product is neutralized with acetic acid and fed into a stripping column (b). Unconverted acetaldehyde is taken overhead and recycled to the reactor (a). The intermediate acetaldol is fed as a bottom product of column (b) into the azeotrope distillation column (c). The aldol is dehydrated, and a crotonaldehyde/water azeotrope distills and is separated into water and an aqueous crotonaldehyde phase containing ca. 10 % water. The water is fed back into the azeotrope column (c), which it leaves as the bottom product. The aqueous crotonaldehyde stream is fed into the rectification column (d). Again a crotonaldehyde/water azeotrope leaves the column overhead and separates into water, which is recycled into the azeotrope column (c), and aqueous crotonaldehyde, which is recycled into the rectification column. Pure crotonaldehyde is taken as a side cut. Heavy ends are taken from the bottom of column (d) and combined with organic residues from the azeotrope column (c) and incinerated. Wastewater from column (c) is treated in a wastewater-purification plant.

An interesting technology is the oxidation of butadiene to its monoepoxide [28], which is analogous to the Wacker–Hoechst process for the oxidation of ethylene to acetaldehyde, followed by isomerization of the butadiene monoepoxide [29], [30] to crotonaldehyde.

Paraldol as a substitute for acetaldol [31] is more interesting for producing cosmetic-grade 1,3-butylene glycol than for crotonaldehyde synthesis.

The catalytic oxidation of olefins [32–34], the dehydrogenation of allyl alcohol with amines [35], hydratization of acetylene [36], or the enzymatic oxidation [37], [38] of 2-butene are so far not of practical importance.

Crotonaldehyde is also a byproduct in the synthesis of 1,3-butylene glycol [31], [39] and in acetic acid synthesis by methanol carbonylation [40], [41]. As a result of incomplete combustion, it is also contained in automobile exhaust gases.

Storage and Transportation. Any alkaline or acidic impurity may cause dangerously exothermic condensation reactions of the crotonaldehyde and therefore must be thoroughly excluded. The solidification and color development of crotonaldehyde during storage and transportation can be avoided by careful exclusion of oxygen or other strong oxidizers and light by using stainless steel or aluminum containers. This prevents formation of peroxides and of iron salts of crotonic acid, which induce darkening and polymerization. With these precautions, crotonaldehyde can be stored and shipped without the addition of inhibitors; otherwise, water and hydroquinone can be used as stabilizers.

Figure 1. Acetaldehyde condensation to acetaldol and dehydration to crotonaldehyde
a) Aldol reactor; b) Acetaldehyde stripping column; c) Azeotrope distillation column; d) Rectification column

Due to the toxic and lacrimatory properties of crotonaldehyde (Chap. 3) its transport is regulated; mailing and air transport are prohibited [4].

1.3. Uses

Large amounts of crotonaldehyde are used for the synthesis of sorbic acid (*trans*, *trans*-2,4-hexadienoic acid), a food preservative, and Vitamin E. Sorbic acid is made by the condensation of crotonaldehyde with ketene in the presence of organic zinc salts, followed by depolymerization of the resulting polyester either thermally or with a mineral acid [42–45].

α-Tocopherol, one of eight naturally occurring substances with vitamin E activity, is synthesized on an industrial scale by the condensation of phytol with 2,3,6-trimethylhydroquinone. The latter is made in four steps from crotonaldehyde and diethyl ketone (→ Vitamins, Chap. 4.) [46].

3-Methoxybutanol is made by addition of methanol to crotonaldehyde [12], [13]. This product and its acetate ester are used as specialty solvents, for example, for the control of viscosity, drying behavior, and gloss of lacquers and varnishes (→ Solvents, Chap. 6.).

Furthermore, crotonaldehyde is widely used for the production of chemical intermediates, such as crotonic acid, which is made by the oxidation of crotonaldehyde (Chap. 2.2). End uses of crotonaldehyde-based intemediates include pharmaceuticals and biocompatible or medical articles [47], [48], agrochemicals [49], [50], resins, polymetric thickeners [51], paints and coatings [52], dyestuffs [53], rubbers [54] and rubber antioxidants [53], gelatin hardening [53], adhesives [55], [56], leather tanning [53], leather and paper sizing [53], metal brighteners [53], lubricants [57], and corrosion inhibitors [58].

Crotonaldehyde is also employed in flavoring agents [53] and as an odorant and warning agent in fuel gases as well as for the manufacture of tear gas [53], as a solvent for purification of mineral and lubricating oils, as a solvent for poly(vinyl chloride) and in polymer technology as a reaction medium [53].

2. Crotonic Acid

Crotonic acid [*3724-65-0*] is the *trans* isomer of the two stereoisomeric forms of 2-butenoic acid. *cis*-2-Butenoic acid is called isocrotonic acid [*503-64-0*] but is not commercially available in larger quantities. Commercial crotonic

acid is a white to yellow solid with a pungent and suffocating odor. Isocrotonic acid is a colorless liquid.

Crotonic acid occurs naturally, e.g., in crude wood distillate and sponges, and it is a component of defensive substances or secretions of various beetles.

Table 1. Physical properties of crotonic and isocrotonic acid [3], [59], [60]

	Crotonic acid	Isocrotonic acid
Boiling point	189 °C, 81 °C (17 mbar)	169 °C
Melting point	72 °C	15 °C
Density (20 °C)	1.018	1.0267
Refractive index n_D	1.4228 (80 °C)	1.4456 (20 °C)
Solubility in water, g/kg	41.5 (0 °C), 94 (25 °C)	
	656 (40 °C), 1260 (42 °C)	
Flash point	88 °C	
Auto ignition temperature	396 °C	
Vapor pressure	24 Pa (20 °C), 880 Pa (70 °C)	
Specific heat	3.031 J g^{-1} K^{-1} (s), 2.072 J g^{-1} K^{-1} (l)	
Heat of combustion	2.00 MJ/mol	2.03 MJ/mol
Heat of fusion	150.9 J/g	
pK_a	4.817 (25 °C)	

2.1. Physical and Chemical Properties

Some physical properties of crotonic acid and isocrotonic are summarized in Table 1.

Crotonic acid crystallizes as white needles or prisms in the monoclinic system. Its solubilities at 25 °C are: in water 9.4 wt %, ethanol 52 wt %, acetone 53 wt %, ethyl acetate 72 wt %, and toluene 37 wt %. The aqueous solution acts as a weak acid. The azeotrope of crotonic acid and water (96.86 %) boils at 99.7 °C.

Crotonic and isocrotonic acid form an eutectic mixture containing 30 % crotonic acid with a melting point of − 3 °C.

Isocrotonic acid is miscible with water and polar solvents. Heating of either or both acids, or treatment with other acids, bases, or UV radiation leads to isomerization, oligomerization, and polymerization.

Isocrotonic acid isomerizes to crotonic acid. The equilibrium between the two isomers is reached between 140 and 180 °C [3]; 3-butenoic acid is a byproduct of this process. The equilibrium mixture has an isocrotonic to crotonic acid ratio of ca. 0.17 : 1.

Both acids can be hydrogenated to crotyl alcohol and butyric acid or oxidized to the peracid. The most important reactions are polymerizations, additions, and esterifications.

Polymerization. Many types of monomers can be copolymerized with crotonic acid (radical mechanism). Important copolymers are formed with vinyl acetate (see Section 2.3).

Additions. Additions to crotonic acid yield 2- and 2,3-substituted butyric acid. Crotonic acid can be hydrogenated catalytically to butanoic acid. The addition of halogens or hydrogen halides to the olefinic double bond leads to the corresponding 2,3-dihalobutanoic acid or 3-halobutanoic acid, respectively. Treatment with OsO_4 or peracids like peroxybenzoic acid yields 2,3-dihydroxybutanoic acid. The addition of ammonia under suitable reaction conditions gives β-aminobutyric acid. Crotonic acid acts as a dienophile in Diels – Alder additions.

Other Reactions. Crotonic acid can be esterified by conventional methods, although the reaction is often slower than with butyric acid due to the conjugated system. Crotonyl halides can be prepared by the reaction of crotonic acid with a corresponding acyl halide; crotonic anhydride by the reaction of crotonyl chloride with sodium crotonate; or the reaction of crotonic acid with acetic anhydride.

2.2. Production

Crotonic acid is prepared on an industrial scale by the oxidation of crotonaldehyde, for instance, by Daicel and Eastman Chemicals. Peroxocrotonic acid is formed as an intermediate, which comproportionates with crotonaldehyde to yield two molecules of crotonic acid:

$$CH_3CH{=}CHCHO + O_2 \longrightarrow CH_3CH{=}CHC(O)OOH$$

$$CH_3CH{=}CHC(O)OOH + CH_3CH{=}CHCHO \longrightarrow 2\,CH_3CH{=}CHCOOH$$

The reaction is typically conducted at low pressure (ca. 1 – 5 bar) and temperatures between 20 and 45 °C. Higher temperatures result in oxidative decomposition. Catalysts such as manganese, cobalt, copper, or thallium salts result in satisfactory conversions and yields even at 20 °C [3], [61], [62] and prevent the buildup of undesired peroxo compounds. In the former Hoechst

process (manganese salts as catalysts, oxidation at 20 °C) no additional solvents were used. A typical raw product contains about 30 % crotonic acid, 1 – 3 % of formic and acetic acids, water, and only traces of isocrotonic acid. This crude product is fractionated at reduced pressure; unconverted crotonaldehyde is recycled to the oxidation reactor.

Isocrotonic acid is removed from the final product by fractional crystallization, yielding crotonic acid with up to 99.9 % purity [63], [64].

On a nonindustrial scale, crotonic acid can be prepared, e.g., by dehydration of 2-hydroxybutanoic acid, by photochemical oxidation or by photochemical oxidation or oxidative irradiation of crotonaldehyde with ultrasound [65], by the isomerization of vinylacetic acid with sulfuric acid [60], by the condensation of acetaldehyde and malonic acid with pyridine as catalyst (85 % yield) [66], by the oxidation of butene with a heteropolymolybdic acid containing catalyst system [67], by the oxycarbonylation of propene with transition metal complex catalysts [68], by the carbonylation of propylene oxide [69], by the reaction of acetic anhydride with acetaldehyde with basic aluminum acetate as catalyst [70], and by the carbonylation of allyl alcohol in a two-phase system with a nickel-containing phase - transfer catalyst (90 % conversion, 68 % yield) [71] or a palladium catalyst [72].

Isocrotonic acid can be obtained by fractional crystallization, rectification or gel filtration from a mixture of the two 2-butenoic acids. On a laboratory scale it can also be prepared from 2-butanone by bromination followed by a stereospecific Favorskii rearrangement [73]. Other methods to prepare isocrotonic acid are reviewed in [74].

Storage and Transportation. Crotonic acid is usually shipped in paper bags with inner polyethylene bags or polyethylene-lined drums. It should be stored in the dark away from bases, oxidants, and reducing agents to avoid polymerizations or other strongly exothermic reactions.

2.3. Uses

The main use of crotonic acid is in the synthesis of copolymers with a variety of comonomers. Especially important are crotonic acid – vinyl acetate copolymers. Trade names include Cevian, Gelva, Mowilith, and Vinac.

Crotonic acid copolymers have a very broad range of applications: paints and coatings [75–78], hot-melt paints [79]; adhesives [80], [81], and hot-melt adhesives [82]; coatings for paper and textiles; flocculants [83], binders for explosives [84], ceramics [85] and agrochemicals [86]; and drilling additives [87].

Crotonic acid has antimicrobial properties and may like its esters be used in deodorants [88], [89], UV absorbers [90] and metal-effect interference pigments [91]. Fatty alcohol esters of crotonic acid are used in the leather industry [92], [93]; the free acid is used in motor fuels [94], [95], for the etching of metal surfaces [96–98], for electrochemical metal deposition [99], and PVC heat stabilization [100].

Several agrochemicals and pharmaceuticals are based on crotonic acid and its anhydride or chloride.

3. Toxicology and Occupational Health

Crotonaldehyde. Perception of the irritating, pungent, and suffocating odor of crotonaldehyde has been reported at thresholds from 0.035 to 0.12 ppm in air [53]. Therefore, crotonaldehyde is used as an odorant and warning agent in fuel or gas [53].

OSHA, NIOSH, and ACGIH have established a permissible exposure limit and TLV of 2 ppm for an 8-h workday [53]. The German TRGS 900 allows a maximum concentration of 1 mg/m^3, the former MAK classification IIIB has been abandoned [4]. Exposure may occur through inhalation, eye or skin contact and by absorption through the skin or ingestion.

Crotonaldehyde is severely irritating to the eyes, mucous membranes, the upper respiratory system and skin in animals and humans. Sensitization may occur. It is classified as a marine pollutant although its 10-d biodegradibility is $>$ 83 % according to OECD 302 B [4].

Effects on Humans. A 10-min exposure to 4 ppm of crotonaldehyde induces lacrimation; conjunctival irritation is caused by only brief exposure to 45 ppm [101], corneal injuries (exposure severity not specified) could be healed in at least eight cases during 48 h.

Effects on Animals and Microorganisms. The following toxicology and ecotoxicology data have been determined:

LC_{50} (rats)	1500	ppm (30 min)	[53]
LC_{50} (rat, oral)	206 – 300	ppm	[4]
LC_{50} (rat, inhalative)	0.29	mg/L	[4]
LC_{50} (fish/*Pimephales promelas*)	0.85	mg/L (96 h)	[4]
LD_{50} (rabbit, dermal)	128 to 324	mg/kg	[4]
LD_{100} (rat, subcutaneous)	180	mg/kg	[102]
EC_{50} (*Daphnia magna*)	2	mg/L (48 h)	[4]
EC_{50} (algae)	0.88	mg/L (72 h)	[4]
EC_{10} (bacteria)	150	mg/L	[4]

10 ppm of crotonaldehyde caused adverse changes in pulmonary performance in rats during a single 200-min exposure [103]; 1650 ppm (10-min exposure) induces respiratory distress, pulmonary edema, bronchiolar damage, excitation, and terminal convulsions [101].

Chronic effects or oncogenic properties [104], [105] are not linked so far to crotonaldehyde exposure, although crotonaldehyde can induce point mutations in bacteria [106] and carcinogen-induced DNA damage [107] and is therefore classified as mutageneous [4].

Crotonic acid. Crotonic acid is corrosive to the eyes (causing pain, blurred vision, deep burns), skin (causing skin burns and pain), and respiratory tract (causing a burning sensation, cough, headache, nausea, sore throat and shortness of breath; these symptoms may be delayed), and on ingestion (causing pain, burning sensation, sore throat, diarrhea, vomiting).

The following toxicology data have been determined in animal experiments:

LD_{50} (rat, oral)	1 g/kg	[108]
LD_{50} (rat, i.p.)	100 mg/kg	[109]

Crotonic acid is formed by fat metabolization [110], and is rapidly converted by enzymes in the liver or other tissues. No cumulative effects are likely after exposure to nonirritating concentrations [3].

Crotonic acid affects plant growth and the germination of seeds [60].

Crown ethers belong to the general group of macrocyclic polyethers. The name crown ethers refers to the crown-like atomic arrangement. The most remarkable property of crown ethers is their ability to yield stable complexes with alkali and alkaline-earth metal ions and ammonium ions. Crown ethers may also act as "second-sphere ligands" of metal ion complexes. Under optimized conditions, crown ethers can be used effectively for ion extractions, but other important uses are, for example, as complexing agents and phase-transfer catalysts in organic syntheses. Besides the characteristics and uses of crown ethers, their production processes and toxicological features are addressed as well.

1. Classification and Nomenclature

Crown ethers [1 – 11] were originally defined as macrocyclic polyethers with the following structure [1]:

where Z = alkylene, arylene, or cycloalkylene

Typical bridging groups are 1,2-ethylene, *o*-phenylene, and 1,2-cyclohexylene, which can also be substituted. In the common crown ethers **1–9** x ranges from 3 to 6. Dioxane ($x = 1$) is not considered a crown ether (→ Dioxane).

Hetero analogues in which oxygen is replaced either partially or completely by other heteroatoms [12], especially sulfur [13, 14] or nitrogen [15, 16], are also known (**10** – **15**) [5, 6, 9]. The heteroatoms can be integrated into heterocycles, as in **15** or can even be a metal center (metallacrown ether) [17, 18]. These hetero crown ethers are also called coronands [5, 19].

13

14

15

Other expanding subclasses in the general group of macrocyclic polyethers are the lariat ethers [20 – 22], in which a crown ether (coronand) ring is attached to one or more donor sidearms, such as **16**, and the spherands [20, 23, 24] having an enforced crown-type cavity, such as **17**. Occasionally, open-chain analogues such as **18** (podands) [25 – 27] and bi- or oligocyclic compounds such as **19** (cryptands) [28 – 30] are also classified as crown ethers [19].

16

17 R = OCH_3

18

19: $l = m = n = 0 – 2$

A more general term applicable in this field of substances is crown compounds [19].

The name crown ethers refers to the crown-like atomic arrangement [1]. A special system of nomenclature is generally preferred to the more complicated IUPAC system (Table 1) [19]. Thus, compound **2**, which contains 5 endocyclic oxygen atoms and a total of 15 atoms in the ring, is usually called 15-crown-5 (or [15]crown-5). Additional substituents or condensation sites such as "benzo" and "dicyclohexano" (older nomenclature: dicyclohexyl or perhydrodibenzo) appear as a prefix. Acronyms are also used for common crown ethers (Table 1). A more recent terminology enables a more precise indication of the type and sequence of the heteroatoms and bridging units (e.g., **14**: 18 O_2NS_2N-2_6-coronand-6⟩) [31]. The phane nomenclature can be used

for benzo derivatives (e.g., **6** 1,4,7,14,17,20-hexaoxa[7.7](1,2)benzenophane) [32].

The crown ethers were first described by C. J. Pedersen [1, 33] in 1967; since then they have been extensively studied by many groups [1 – 11].

2. Physical Properties

Nomenclature and physical data for important crown ethers are given in Tables 1 and 2, respectively.

Crown ethers of the ethylene oxide oligomer type (**1** – **4**) are colorless, odorless, viscous liquids or solids with a low melting point. They are strongly hygroscopic and readily soluble in most organic solvents and in water [6, 11].

Crown ethers with condensed aromatic rings (**5** – **7**) are colorless, barely hygroscopic, crystalline compounds. At room temperature they have poor solubility in water, alcohols, and many other common solvents [6]. They are readily soluble only in halogenated hydrocarbons, pyridine, and formic acid.

Crown ethers with alicyclic bridges (**8**, **9**) have much better solubility in hydrocarbons and much poorer solubility in water than the ethylene oxide oligomers [6].

The solubility of crown ethers increases markedly if salts are added [1, 6, 11], e.g., 25-fold for dibenzo-18-crown-6 (**6**) in MeOH after addition of KF [6]. The increase depends on the type of salt used. Conversely, presence of the crown ether increases the solubility of the salt (see Chap. 4).

3. Chemical Properties

Like simple dialkyl ethers, aliphatic and alicyclic crown ethers are chemically stable [6]. Aromatic crown ethers react like anisole or veratrole, i.e., they can be halogenated or nitrated and they react with formaldehyde [1]. Hydrolysis takes place only in special cases [36, 46]. Crown ethers are also thermally stable; dibenzo-18-crown-6 (**6**) can be distilled at 380 °C without decomposition [39]. With hydrogen ions [47] and in the presence of Lewis acids ($AlCl_3$, $TiCl_3$), oxonium compounds are formed [48]. The hetero derivatives (**10** – **15**) are usually more reactive than the classical crown ethers. Aza analogues are strong bases and react with acids to form salts.

4. Crown Ether Complexes

The most remarkable property of crown ethers is their ability to yield stable complexes with alkali and alkaline-earth metal ions and with ammonium ions [5, 11, 49, 50]; complexes with other

main group metal, transition metal, lanthanide, and actinide ions are also possible [51], as well as complexes with organometallics [52]. Numerous complexes of crown ethers with nonionic organic molecules are also known [53 – 55].

Crystalline complexes of crown ethers and metal ions (Table 3) are obtained by mixing the two components in a common solvent [1, 6]. Both metal complexes and H-bonded complexes that are stable and strongly bound can also be generated in the gas phase from ion molecule reactions [56]. The solid complexes have higher melting points than the free crown ethers (see Table 1). The stoichiometry of the complexes (crown ether: salt = 1 : 1, 2 : 1, or 1 : 2) is largely determined by the fit of crown ether cavity and cation diameter [57 – 59] (see Table 4). Structure determination by means of X-ray diffraction [51, 57, 60 – 63] has confirmed that in the 1 : 1 complexes the cation is located inside the crown ether ring. For the 2 : 1 complexes, sandwich structures were found. In the 1 : 2 complexes, two cations are located inside the crown ether ring. Complexes in which the cation is surrounded by a cage-like structure have also been described. In all cases, the cations are coordinated to the ether oxygen atoms which point into the ring. Hydrogen bonds are effective in complexes with ammonium ions. Frequently there is also contact with the counterion. Moreover, crown ethers may act as "second-sphere ligands" of metal ion complexes [64 – 66].

In solution, the complexes exhibit varying degrees of stability [2, 44, 57, 67] (Table 5). They are most stable under the following conditions:

- Optimum ratio of cation diameter to cavity diameter
- Optimum number of ether oxygens capable of coordination
- Strongly basic ether oxygens
- High charge density at the cation
- Low polarity of the solvent
- Lipophilic, polarizable anion

Nitrogen (e.g., **11**) and, especially, sulfur (e.g., **13**) decrease the stability of alkali and alkaline earth metal ion complexes. Conversely, complexation with Ag^+ or other heavy-metal ions and with ammonium ions is enhanced [2, 67]. The effect of heterosubstitution on the stability of 18-crown-6 complexes is shown in Table 6. Pyridine rings (e.g., **15**) increase selectivity for sodium ions [67]. Recently, seleno-containing crown compounds were shown to complex C_{60} [68].

[a] In methanol.
[b] In water.

The stability constants reflect the ion selectivity of the crown ether [49, 57]. A quantitative measure is the ratio K_{M1}/K_{M2} (M1 = cation 1, M2 = cation 2). Ion selectivity depends to a large extent on the solvent; in certain cases it can even be reversed through a change of solvent. For example, in water, 18-crown-6 (**3**) complexes of barium ions are more stable than those of potassium ions (K_{Ba}/K_K = 1.84), whereas in methanol the potassium complexes are more stable (K_{Ba}/K_K = 0.95) [12]. In multiphase systems that are suitable for selective salt extractions — e.g., H_2O, salts/CH_2Cl_2, crown ether — ion selectivity is determined by the relative degree of salt transfer [69]. Effective extraction requires large anions that are strongly polarizable (e.g., picrate), a highly lipophilic crown ether, and a high stability of the complex in the organic solvent.

The thermodynamic characteristics of a large number of crown ether complexes in various solvents have been determined [49, 57, 67]. The

kinetics of crown ether complexation have also been studied [57, 67, 70].

5. Production

The most important methods for the production of crown ethers are analogous to the Williamson ether synthesis [9 – 12, 71 – 73]. The ether rings are formed by reaction of diols with bifunctional components that possess terminal leaving groups such as chloro or tosylate (Eq. 1):

(1)

The reaction is carried out in the presence of a base, e.g., an alkali metal hydroxide or carbonate, cesium fluoride, potassium *tert*-butoxide, or sodium hydride. *n*-Butanol, *tert*-butanol, tetrahydrofuran (THF), and, less frequently, dimethylformamide (DMF) or dimethyl sulfoxide (DMSO) are used as solvents. Cyclization can take place in a single step (Eq. 1) or in several steps:

(2)

Protecting groups may be necessary. A one-component method in which the leaving group X is produced from the diol in an intermediate step is also known [6]:

(3)

A template effect, i.e., enhancement of yield and reaction rate by cations that are dimensionally compatible with the crown ether being produced, is often observed [74].

A different production method is based on the cyclooligomerization of oxirane [72, 75]:

(4)

This also involves template participation [74]. The oxirane method is suitable only for the production of unsubstituted aliphatic crown ethers of a limited range of ring sizes, e.g., 12-crown-4 (**1**), 15-crown-5 (**2**), and 18-crown-6 (**3**). The Williamson procedure is generally applicable and yields both aliphatic and aromatic crown ethers [71 – 73]. Crown ether sulfides are produced similarly (nucleophilic substitution by a thiol group) [13, 14, 71]:

(5)

Synthesis of crown ether amines proceeds via a cyclic diamide or a cyclic bis(tosylamide) [16, 72, 73]. Crown ethers with cyclohexane bridges are obtained through catalytic hydrogenation of the appropriate aromatic compounds [76].

Commercial Products. Most of the crown ethers **1** – **15** are commercially available (Chap. 1); the preparations are usually of > 98 % or > 99 % purity (specification by gas chromatography). Cyclohexano derivatives contain up to 2 % of the corresponding benzo crown ether. The most important suppliers are ABCR, Acros Organics, Alfa Aesar, Avocado, Fluka, ICN, Lancaster Synthesis, Merck, Sigma Aldrich, Strem Chemicals, and TCI [73].

6. Uses

Crown ethers are useful in many fields of application [77 – 79]. Important uses are as complexing agents and phase-transfer catalysts in *organic syntheses* [5, 80 – 84]. They solubilize inorganic salts that are needed as reactants in organic solvents. This amounts to activation of the anion (reagent) [85 – 87]. The main advantages

as compared with phase-transfer catalysts such as quaternary ammonium salts are the greater activating effect on the anion (naked ions) and the absence of foreign ions, the crown ether being neutral. In addition, phase transfer directly from the crystal into the organic phase (solid – liquid phase transfer) is usually possible.

Table 7 illustrates the preparative usefulness of crown ethers. Modern laboratory synthesis, including preparation of natural compounds, would be unthinkable without crown ethers [87]. The industrial application is especially in the manufacture of polymers and polycondensates [95 – 97]. In principle, any reaction involving the participation of ions can be influenced by crown ethers [5, 77].

Another important field of application is in *chemical analysis* [98 – 102]. The ion selectivity of crown ethers permits the concentration, separation, and masking of ions and the determination of ion concentrations. Suitable methods include ion extraction [69], ion chromatography [104 – 106], capillary electrophoresis [104], and membrane transport [99, 107]. It is possible in this way to separate traces of Sr^{2+} from an excess of Ca^{2+}, and even $^{44}Ca^{2+}$ from $^{40}Ca^{2+}$ or other metal ion isotopes [108]. Heterosubstituted crown ethers are mainly used in the analysis of transition-metal ions [100]; they are suitable for the masking and decontamination of environmentally and physiologically damaging heavy-metal ions [109], including separation of cationic fission products from nuclear waste [110]. A microassay of Na^+ and K^+ in blood and urine has also been developed [98, 111]. Crown compounds for the stereognostic coordination of rare metals have been designed [112]. Many potentiometric chemical [111, 113, 114] and optical sensors (luminescent and chromogenic probes) [115 – 117] for metal ions are based on crown compounds.

Recent developments in the area of anion recognition and sensing have produced a variety of receptors for anions, some containing crown subunits, and have been used to separate anions [118]. Heterotopic receptors based on crown compounds with specific cation and anion binding sites that behave as recognition systems for salts (ion pair binding) have been prepared and used [119, 120].

Moreover, crown ethers can be used in developing effective sorbents for separation of organic compounds [53, 55, 121]; chiral derivatives of crown ethers [23, 122, 123] result in racemate splitting (optical resolution) [98, 101].

Aside from these applications in chemical synthesis and analysis, crown ethers can be used for imaging and targeting in the diagnosis of diseases [124], for molecular packing, storage, protection and stabilization of compounds [125], as aids in detergent and surfactant industries, in electroorganic synthesis and galvanizing, in the manufacture of organic conductors and anticorrosives [77], as well as in the preparation of liquid-crystalline phases [126] and Langmuir or Langmuir-Blodgett films [127]. Figure 1. Luminescent probe (**20**), liquid crystalline (**21**), organo gelator (**22**), and SAM-forming (**23**) crown-type compounds. Prototype [2]catenane (**24**) and [2]rotaxane (**25**) structures contain crown ethers as an assembly group

Table 8. Toxicological data for crown ethers [6]

Crown	Acute toxicity,		
	oral		dermal
12C4 (**1**)	LD_{50}	3.15 ± 0.06 g/kg [a]	
15C5 (**2**)	LD_{50}	1.02 ± 0.1 g/kg [a]	
18C6 (**3**)	LD_{50}	0.705 ± 0.08 g/kg [a]	LD_{50} 200 mg/kg [b]
DB18C6 (**6**)	LD_{50}	> 300 mg/kg [a]	ALD [e] 7.50 g/kg [c]
	LD_{50}	11 g/kg [b]	
DB24C8 (**7**)	LD_{50}	> 300 mg/kg [a]	
DCH18C6 (**8**)	LD_{50}	> 300 mg/kg [a]	ALD [e] 130 mg/kg [d]
	ALD [e]	300 mg/kg [b]	

[a] Mouse.
[b] Rat.
[c] Guinea pig.
[d] Rabbit.
[e] ALD = approximate lethal dose.

on self-assembled monolayers (SAMs) that contain crown ether subunits [128] or monolayer- and mixed-monolayer-protected clusters (MPCs and MMPCs) involving crown compounds [129] are promising fields of application. Fullerene [130, 131] and dendrimer structures [132, 133] have been combined with crown ethers in order to modify their properties. Moreover, crown-appended gelators have been utilized as building blocks in organogels [134] and as templates for sol-gel transcription [135]. Crown-type compounds have also pioneered new photochemical and photophysical devices [136], including molecular machines [137], e.g., based on catenanes and rotaxanes [138], and are promising in many other technologies emerging from supramolecular chemistry [78]. Some exemplary structures relating to these compound types that involve crown ether subunits are shown in Figure 1.

With reference to life, crown compounds have been explored in a number of biological contexts [139]. They have shown activity in toxicity studies to bacteria [140] and cancer cell lines [141]. Others were found being able to intercalate into DNA and to protect the double helix from enzymatic cleavage [142] or show activity against AIDS related lymphoma cell lines [143]. Certain crown ethers were found to accelerate the reaction rate of lipase enzymes in organic solvents [144] or were shown to form channels in the bilayer of living human embryonic kidney cells and may thus hold potential under the developing concept known as "channel replacement therapy" [145].

7. Toxicology and Occupational Health

The oral and skin toxicity of crown ethers is much greater than that of ordinary ethers [9, 146]. As complexing agents they cause damage to the body's ion balance [109]. The main effects are therefore on the central nervous system [6]. Typical sublethal intoxication phenomena include rapid breathing, nervous tension, lack of coordination, tremor, and lassitude. Many crown ethers also damage the eyes and skin [39]. Lethal toxicity data for common crown ethers can be found in Table 8.

Protective clothing and goggles must be worn when crown ethers are handled [146]. Contact, especially with the eyes, should be avoided. The danger of intoxication by inhalation is greatest for 12-crown-4 [6, 148].

According to the RID and ADR transport regulations, crown ethers fall into class 6.1. Incineration is prescribed for the disposal of residues and waste.

This article summarizes the theory and practice of the growth of single crystals. Today, the growth of crystals having dimensions of some hundred millimeters in diameter and weights over 200 kg under extreme pure conditions is well-matured in industrial scale. The major user of the crystals is the electronics industry.Growth of crystals demands theoretical knowledge of thermodynamics, kinetics, and transport processes. In practice, some general aspects have to be considered, including choice of raw materials, conditions, methods, and characterization. The industrial and laboratory techniques of crystal growth are discussed. Economical aspects dominate the developments in the future, that is, growing of larger crystals at higher quality to raise yields and device performance. Furthermore, the demand for tighter specifications and increasing range of materials and uses will require more sophisticated methods and an extensive use of automation.

Symbols:

a	lattice constant, crystal radius
A	radius of fluid, constant
b	Burger's vector
B	magnetic induction
c	concentration
C	specific heat
D	diffusion coefficient
f	growth rate
g	acceleration due to gravity
G	free energy, shear modulus
h	height of nucleus, heat transfer coefficient
H	enthalpy, depth
J	flux
k	segregation coefficient
K	thermal conductivity
L	face size
N_{d}	dislocation density
Q	addition rate of particles
S	entropy, radial spacing
t	time
T	temperature
u	number of nearest neighbors
V_{m}	molar volume
v	velocity of growth face, flow velocity
w	number of nearest neighbors on surface
x	atom fraction
α	expansion coefficient, crystal face parameter, ratio of spacing
β	volume expansion coefficient
γ	surface tension
δ	thickness of boundary layer
η	dynamic viscosity
$\varkappa$	thermal diffusivity
ν	kinematic viscosity
λ	layer spacing
ρ	mass density
σ	relative supersaturation, strain
τ	time constant
ω	rotation rate
∇^2	Laplacian operator $\left(\frac{\partial^2}{\partial x^2}+\frac{\partial^2}{\partial y^2}+\frac{\partial^2}{\partial z^2}\right)$

1. Introduction

This article summarizes the theory and practice of the growth of single crystals. Consideration is restricted to cases in which the ultimate product exploits *crystallinity; industrial crystallization,* which uses the crystallization process to purify or to obtain a product in an acceptable form (e.g., granulated sugar), is excluded here, but treated in → Crystallization and Precipitation.

1.1. Historical Aspects

Crystals have been grown on a commercially significant scale since about 1950. Before this, almost the only significant activity was the growth of rubies for watch and clock bearings and, after 1940, defense-related activities (e.g., piezoelectric crystals for sonar transducers). However, the origins of the technology occurred much earlier.

According to references [1 – 4] and the sources quoted, the use of crystallization for the purification of salt can be traced back to 2700 B.C., growth from aqueous solution was being studied systematically in 1600 A.D. and high-temperature solution growth in 1800; and by about 1850, melt growth was a process of scientific interest.

Commercial exploitation on a small scale started around 1900 with the "Geneva" rubies grown by the Verneuil process (see Section 6.5), first used for jewelry and later for bearings in watches and similar instruments. Until quite recently, there was a reluctance to use artificially grown crystals as jewels; now, however, about half the rubies used as jewels are synthetic, and materials which do not exist naturally are common; cubic zirconia, for example, is in many ways a better gemstone than diamond.

VERNEUIL's first paper [5] on the method that carries his name was published in 1902; the second, more informative paper [6] appeared in 1904. During the next 44 years (up to the invention of the transistor in 1948), many of the methods discussed in Chapters 6, 7, 8 and 9 were developed. Thus, SPEZIA's work on hydrothermal growth [7 – 9] was published between 1905 and 1908. The foundations of growth from the solid were laid in 1912 [10] and 1918 [11]. Also, in 1918 CZOCHRALSKI's paper [12] on crystal pulling from the melt was published. Before that the growth of crystals from the top into the melt was introduced in 1916 by NACKEN [13]. A similar technique with seed selection was then developed by KYROPOULOS in 1926 [14]. The decomposition of halides was used to grow crystals from the vapor in 1922 [15]. After TAMMANN [16] in 1914 studied for the first time the

unidirectional solidification of metals in small vertical tubes, the crystallization of bulky melts in containers was described in 1925 by Bridgman [17] and Stober [18], and the technique was improved in 1936 by Stockbarger [19] using a two-zone furnace. Zone melting of metals was initiated in 1928 by Kapitza [20].

Over the same period, much of the theoretical base of crystal growth was also laid. Thus, in 1904, Nernst [21] applied boundary layer ideas to crystal growth, and the basic ideas of the kinetics of the growth of perfect crystals were formulated in 1922–1928 by Volmer, Klossel, and Stranski [22 – 24]. Other theoretical aspects were treated by Gibbs, Curie, Wulff, and Kaishev.

The year 1949 can be regarded as a watershed [25]; reference [26] gives an account of the state of knowledge at that time and the motivation of workers in the field, who were mainly engaged in scientific pursuits, i.e., studying crystals and their growth or using crystals in scientific instruments. The synthetic crystals of interest in 1949 were mostly semiconductors (especially germanium). After 1949, most workers were employed directly or indirectly because crystals could be used in commercial products. As a consequence, at this time the Czochralski method, being then as now the most productive bulk crystal growth method (Section 8.1), was extended to large-scale production. In 1950 Teal and Little [27] started the pulling of relatively large germanium crystals for the first transistors at Bell Laboratories. Shortly after, in 1952, Teal and Buehler [28] adapted the Czochralski method for production of silicon crystals. The crystals were real (i.e., dirty, strained, and inhomogeneous as compared to ideal crystals), and these imperfections had to be controlled. For many purposes, one impurity atom per million host lattice atoms is of no importance; however, in a semiconductor device, unwanted impurity atoms at this level can have catastrophic consequences.

Semiconductor devices are made from crystals containing specified amounts of desired impurities (dopants) and preferably no other impurities at a detectable level.

The need for purity led to the invention of zone refining [29] and the floating zone process [30, 31]. Zone refining is a process in which a molten zone is passed along a bar. Impurities are usually more soluble in the melt than in the solid, so the zone tends to carry the impurities with it. Passing a succession of zones can produce extreme purity: levels of 1 impurity atom in 10^{10} host atoms have been claimed, but measurement of impurity contents below 1 in 10^8 is difficult. For details of zone refining, see Section 6.4 and [32].

Another impurity-related problem involves the desired distribution of dopants. In 1953 it was shown [33, 34] that in many situations the amount of impurity incorporated depends on the phase diagram, the growth rate, and the thickness of the boundary layer at the growth face. The general relation between impurity concentration and growth rate is still an unsolved problem (see Chap. 4).

The causes of strain and crystallographic imperfections are now known and, at a price, certain crystals can be grown without dislocations and with small (say $< 10^{-5}$) built-in strain.

Chapters 2, 3, 4 of this article summarize the theoretical problems solved in the last few decades. Chapters 5, 6, 7, 8, 9 discuss practical techniques, which have changed markedly. For example, in 1949 crystal sizes were typically a few millimeters. Current linear dimensions are 100 times larger. In 1949, a temperature of 1000 °C controlled to $\pm$ 1 °C represented good technology; today, control to $\pm$ 0.1 °C is routine, and good technology can improve this by a factor of at least five. In 1949, raw materials containing less than 10–100 ppm of impurities were rare and expensive; today, levels over 1 ppm are unacceptable for many applications. To maintain high purity, clean ambients (e.g., laminar flow cabinets if not full clean room facilities) are common. Meanwhile, the growth of crystals with dimensions of some hundred millimeters in diameter and weights over 200 kg under extreme pure conditions is well-matured on industrial scale. Worldwide, there are nearly hundred companies dealing with production of metal, semiconductor, and dielectric crystals, mostly, combined with subsequent highly precise crystal cut and pieces polishing before sale. Yearly, the advanced semiconductor magazin *III-Vs Review* publishes a special company directory (see, e.g., [35]) with numerous informations on company profiles and product offers.

In order to meet the rapid developments of device dimension reduction and, especially, nanotechnology during the last decade the growth of

crystals with nm and μm dimensions have come to the for. Special target is their multiple arrangement in well-ordered patterns, e.g., by the principle of self-assembly [36]. Beyond the traditional transitions between two phases, the three-phase sequence Vapor-Liquid-Solid (VLS) mechanism (see 8.4) to form nanowhiskers of different materials is more and more applied. Although the VLS mechanism is already known for a long time and was experimentally introduced in 1964 by Wagner and Ellis [37], it has now a renaissance on a much higher technological level. More details are treated in, e.g., (→ Crystallization and Precipitation). History, fundamentals, technological growth aspects, and applicabilities of fiber crystals with diameters in μm dimensions are summarized in the monograph *Fiber Crystal Growth from the Melt* [38].

Finally, the epitaxy techniques for growth of monocrystalline thin films and stacks of quasi two-dimensional thin layers from alternating materials (i.e. multi-quantum wells), showing new physical properties on the nanometer scale, have been developed into the challenging field of quasi-two-dimensional crystal growth with important technological applications in micro- and optoelectronics. Since the first experiments by liquid-phase epitaxy (LPE) [39], chemical vapor deposition (CVD) [40], metal organic chemical vapor deposition (MOCVD) [41] in the 1960s, and molecular beam epitaxy (MBE) [42] in 1975, the capabilities of the methods and device quality have been markedly improved. Even combined methods like MBE with metal organic precursors (MOMBE) [43] are now under investigation. Nowadays, the growth of epitaxial diamond films from an activated vapor phase under low-pressure conditions is possible [44]. An overview on modern epitaxy techniques and applications is given in [3, vols. 3 a, 3 b]. Here only some introductory aspects are referred to in Chapter 8 (see also → Semiconductors, Chap. 5, → Silicon, Chap. 4.2.5, → Thin Films, Chap. 1.4).

1.2. Uses of Single Crystals

An ideal crystal is an infinite array (lattice) of atoms, arranged in patterns that repeat in all three spatial dimensions with uniform repeat distances; these lattice spacings are usually a small number (about 10) of interatomic distances. Lattice spacings for inorganic materials range from about 2.5×10^{-8} to 3.5×10^{-7} cm. Lattice spacings for organic materials involving macromolecules can be much larger (up to 10^{-5} cm for polymers, proteins, and viruses).

Real crystals are finite, and the effects of the surfaces can be detected in some cases. Real crystals also have some unfilled lattice sites (vacancies) and atoms in some sites that are not part of the ideal lattice (interstitials). The number of these point defects depends on the temperature and on the growth conditions or the post-growth conditions in which the crystal comes to equilibrium with its ambient. At low temperatures, the time taken to attain equilibrium can be very long (e.g., years at room temperature). In addition to these thermodynamically predictable point defects, most crystals contain impurity atoms and molecules as well as line defects (dislocations). Except for elemental silicon and germanium, multicomponent bulk crystals (compound semiconductors, oxides, fluorides, etc.) contain dislocations that are mostly inimical to various types of devices due to their surrounding stress field and electrical activity. Additionally, they act as getters for excess and impurity atoms, and this often leads to precipitations (three-dimensional defects). In most cases, characteristic dislocation arrays, such as cellular and grain structures, are formed, which constitute low-angle grain boundaries. Samples containing low-angle boundaries are strictly polycrystalline, but for many purposes, boundaries involving angular changes of about $< 1°$ are acceptable. However, give the increasing demand for nearly perfect highly integrated thin-film devices with high parameter reproducibility, the presence of a network of subgrains, tilted even by lower angles (down to 20 arcsec), is now one of the most serious defects in substrate compound crystals that can significantly impair epitaxial growth and cause scattering of electronic device parameters. Hence, key targets of the crystal grower are the avoidance of subgrain structures and the achievement of homogeneous distribution of the minimum possible number of dislocations. The other two-dimensional sheet defect is a twin plane involving a rotation or reflection of the lattice structure. Samples containing twin planes are not single crystals in the

sense used here, and such samples are unacceptable for many applications.

The existence of long-range order (or the absence of short-range disorder) gives crystals their valuable properties, such as the absence of scattering for long-wavelength photons and particles (e.g., the intrinsic or extrinsic carriers in semiconductors). Here, long means large compared to the interatomic spacing. For photons (e.g., X-rays) and particles (e.g., neutrons and electrons) with wavelengths comparable to the interatomic spacings, systematic interference effects (loosely called diffraction) occur if the wavelength λ and angle θ to the atomic planes fulfill the Bragg condition

$$n\,\lambda = 2d\sin\theta \tag{1}$$

where n is an integer. This property leads to many uses in scientific instruments.

Table 1. Some uses of crystals

Property exploited	Device	Crystals used
Spatial repetition	X-ray prisms	lithium fluoride
	neutron collimators	metals
Absence of	turbine blades	metals
short-range disorder	gramophone styli	sapphire
(giving strength)	bearings	ruby
	tape heads	ferrites
	wire drawing dies	diamond
	abrasives	diamond, sapphire
Uniformity of	lenses, prisms, and	alkali and alkaline
(eliminating scatter	optical windows	earth halides
electromagnetic	lasers	yttrium aluminum
waves)		garnet
	microwave filters	yttrium iron garnet
Uniformity	transistors, diodes,	silicon, gallium
(eliminating scatter of	thyristors, and	arsenide, gallium
charge carriers)	integrated circuits	nitride, silcon carbide
Anisotropy	resonant filters,	quartz, lithium
(allowing exploitation	delay lines	niobate, zinc oxide,
of vector and tensor	Nicol prisms	fluorite
properties)	ultrasonic transducers	Rochelle salt
	gramophone pickups	lithium sulfate
	laser frequency	potassium
	converter	dihydrogenphoshate,
		barium borate

The existence of long-range order which differs with direction leads to anisotropy of crystal properties. Anisotropic properties are useful, for example, in optical polarizers. Even cubic crystals exhibit some anisotropic properties because they are not completely symmetrical (some have no center of symmetry). The absence of a center of symmetry can lead to useful pyroelectric properties (i.e., the appearance of electric charge on some surfaces of crystals that have been subjected to a change in temperature) or piezoelectric effects (the appearance of charge on the surface of crystals subjected to mechanical strain).

Finally, the absence of short-range disorder can give crystals great mechanical strength: no internal sites exist for the nucleation or easy propagation of cracks.

Table 1 contains some examples of the range of applications and typical materials used in these applications. The list is not exhaustive, and interested readers should consult the appropriate contributions in this encyclopedia and standard texts on optics, X-ray and particle diffraction, crystallography, solid-state physics, and the strength of materials. In many applications, crystals offer more than one advantage; in particular, the absence of scattering effects is often a significant advantage of single crystals that are used for some other primary reason.

1.3. Specification of Crystals

Like any other product, crystals should be produced to a specification, but this is not always easy: factors influencing device performance and yield are not always known, and changes in fabrication techniques may call for a material meeting a radically changed specification. Thus, from the producer's point of view, a user's specification "suitable for the application" may be variable and dependent on factors of which he has no knowledge. Similarly, a specification "best available" (implying as pure and as perfect as possible) may also be unsatisfactory: the user's processes might rely on some unspecified impurity or depend on the existence of some imperfections which absorb undesired impurities or modify properties (e.g., diffusion, wettability). The factors that must generally be specified are:

Dimensions and tolerances
Orientation and its accuracy
Gross perfection (low-angle boundaries, twins, inclusions–sizes and volume density)
Crystallographic perfection (dislocation density)
Composition (major component homogeneity)
Dopants (concentration, distribution)

Impurities (maximum concentration of undesired impurities, maximum concentration of all other impurities specified as a total)

In particular cases, other factors may have to be included, and the list will obviously be lengthened if the producer does any post-growth processing such as trimming to size, slicing, or etching. The specification should also include the nature and number of tests to be done. The problems of characterizing crystals are briefly discussed in Section 5.5.

1.4. Commercial Aspects

Three types of organizations are engaged in growing crystals:

1) Organizations that specialize in crystal growth and supply crystals to other user organizations
2) Organizations that grow crystals in-house for their own use
3) Organizations that investigate crystal growth

From the worldwide data available, about 500 organizations can be identified that are interested in crystal growth; of these, perhaps 300 are commercial organizations of categories 1) and 2). Few organizations interested commercially in crystal growth employ more than 50 people who work on crystal growth. Academic teams tend to be small (rarely more than 10). Thus, about 15 000 people in industrial organizations are involved with crystal growth, as well as perhaps another 2000 in academic institutions.

The worldwide output of the industry is about 25 000 t of crystals per year. The major user of these crystals is the electronics industry, which consumes about 16 000 t of silicon (mostly grown by the Czochralski technique), 2500 t of quartz (grown hydrothermally), and 800 t of pentelides (pnictides), such as GaAs, InP,GaP, CdTe, or ZnTe grown by the Czochralski and vertical Bridgman techniques. The current market for ZrO_2 skull-melted crystals, over 98 % of which are fabricated into gemstones, amounts to about 1000 t. The engineering industry uses about 2000 t of slowly cooled, nearly single crystal alloys for highly stressed components and 100 t of nonmetallic crystals for bearings, dies, and tools. About 2000 t of low-quality metal crystals are used in transformer cores and components for electric motors. The optical industry uses about 400 t of assorted halides and some silicon or germanium for windows, prisms, and lenses; other crystals, such as ruby or yttrium aluminum garnet, for lasers; lithium niobate, and ammonium and potassium dihydrogen phosphates for various electrooptic devices. Crystals in common use in smaller amounts are triglycine sulfate (for pyroelectric devices); various chalcogenides, such as ZnS or CdTe, for optical components or $Cd_x\ Hg_{1-x}\ Te$ for infrared detectors; and lithium tantalate for optical and pyroelectric devices. Altogether, about 200 materials are available commercially as single crystals. Most are used at very low rates ($<$ 1 t/a).

When methods are ranked by annual mass produced, the Czochralski technique is first (about 40 %); other melt growth methods (predominantly the Bridgman technique coming to the for even since the last decade as electronically controlled gradient freeze version) produce another 35 % (increasing), solid-state growth accounts for perhaps 12 %, the hydrothermal technique produces about 8 %, and other solution growth techniques account for almost all the remaining output. Perhaps 1 % is grown from the vapor phase.

Melt growth usually has the highest volume growth rate. Quartz can only be produced hydrothermally. Solution growth techniques are usually inexpensive in terms of capital and labor costs. Vapor growth tends to be both slow and expensive. However, both high-temperature solutuion (flux) and vapor growth are increased applied for production of numerous modern semiconductors with extremely high melting points (over 2000 °C), such as SiC, GaN, AlN, being important materials for high-power microelectronics and blue-violett wave regions. For further discussion, see Section 5.4.

When methods are ranked by value, the order of importance is melt growth (about 50 %), solution growth including hydrothermal processes (25 %), vapor growth (15 %), and solid-state growth (10 %). However, this presentation is misleading because a significant fraction (about one-quarter) of the melt-grown crystals are used to provide substrates for the vapor and solution growth of epitaxial layers. The total value of thin layers and their substrates is about 25 % of the value of all the crystals grown.

1.5. Sources of Information

The primary literature (research papers) on crystal growth is extensive: about four papers are published every day on topics relevant to this article, the majority in three international journals (*Journal of Crystal Growth*, *Crystal Growth Design*, and *Crystal Research Technology*, formerly *Kristall und Technik*) and a limited number of conference proceedings. Chemical Abstracts offers *CA Selects Crystal Growth*; this service covers a rather wide field (e.g., industrial crystallization, geological and biological crystallization, as well as the growth of single crystals), allows most of the primary papers to be recognized, covers the patent literature, which is an important source of practical information, and serves as an aid in locating the secondary literature.

Nowadays the abstracts of most current publication and patent citations on crystal growth and epitaxy can be obtained from international databases (e.g., INSPEC with about 4000 journals, Chemical Abstract Service, CRYSTMET, GMELIN, for example) via on-line internet suppliers (e.g., FIZ Karlsruhe).

The secondary literature may be divided into two sections: small area reviews and monographs. Small area reviews are also concentrated; they appear as invited papers at conferences (often in special issues of the *Journal of Crystal Growth*) and in the review journals *Progress in Crystal Growth and Characterization* (Pergamon, Oxford) and *Materials Science & Engineering* (Elsevier). In the 1970s and 1980s numerous reviews were published in a limited number of book series, for example, the series *Crystals* (edited by M. C. Freyhardt) published by Springer (Berlin) or the North Holland (Amsterdam) series *Current Topics in Materials Science* (edited by E. Kaldis).

Fundamental and methodical aspects are reviewed in the *Proceedings of the International Summer Schools on Crystal Growth* (ISSCG) triennially organized by the International Organization of Crystal Growth (e.g., *Theoretical and Technological Aspects of Crystal Growth*, edited by R. Fornari and C. Paorici, Trans Tech Publications, 1998) and *Crystal Growth - from Fundamentals to Technology*, edited by G. Müller, J.-J. Metois and P. Rudolph, Elsevier, 2004). A special chapter on crystal growth of materials treating fundamental and experimental aspects of production of nearly all important substances is included in the *Encyclopedia of Materials: Science and Technology* Elsevier, 2001.

The literature in monograph form is also extensive. There are texts [45, 46] for amateurs or students not specializing in crystal growth. More serious students wanting a broad view should turn to [4, 47 – 51]. Specialists have a wider selection: thus, on low-temperature solution growth, [26] still has much to offer; references [52 – 54] contain much useful material. The last [54] also covers melt growth, as do [55] and [56]; while these three discuss high-temperature solution growth, the standard text is [57]. For vapor growth, consult [58]. Most texts give some account of the theory of the subject, but [59] is the standard text. A number of highly specialized texts contain pertinent information; for example, [60] covers growth in gels (solution growth in the absence of convection), and the growth of polymers (growth controlled largely by the stereochemistry of the molecules) is discussed in [61].

Historical important papers are collected in the book *50 Years Progress in Crystal Growth*, Elsevier, 2004 edited by R.S. Feigelson. In *Bulk Crystal Growth of Electronic, Optical and Optoelectronic Materials*, John Wiley and Sons, 2005, edited by P. Capper, 17 authors summarize the state-of-art of single crystal production and characterization of semiconductors, sapphire, fluorides, scintillator materials, and quartz crystals. Technological aspects of growth and wafer preparation are reviewed in 29 chapters, written by numerous well-known specialists in *Crystal Growth Technology*, Wiley VCH, 2006 edited by H. Scheel and T. Fukuda. An extensive modern compendium comprising three volumes with a total of about 2500 pages was edited during the period of 1993–1994 by D. T. J. Hurle (*Handbook of Crystal Growth*, North-Holland, Amsterdam). Seventy four authors contributed fifty-eight chapters to this almost complete compilation on fundamentals, bulk crystal growth, and epitaxy, which is undoubtedly the leading standard work on these fields at present and will be for some time to come.

Because it is now possible to describe crystal growth processes in a nearly quantitative manner, there is a need for numerical data on physical properties and phase diagrams. The texts

just quoted suggest some sources and others are given in later sections. There are two relevant on-line data banks such as the *Electronic Materials Information Service* (IEE, Station House, Nightingale Road, Hitchin, Herts SG 5 IRJ, United Kingdom) or *EVITHERM Date Centre*, which give relevant physical property data and *MTDS* (National Physical Laboratory, Teddington, Middlesex TW 11 OLW, United Kingdom), which gives thermodynamic data; [62] lists a series of relevant off-line data centers. In 2005, the special book on compound semiconductor material data *Properties of Group-IV, III-V and II-VI Semiconductors* was published by John Wiley and Sons.

2. Thermodynamic Aspects

2.1. Free Energy and Driving Force of Crystallization

The precondition for crystallization of a stable solid phase from a metastable fluid (starting) phase is deviation from thermodynamic equilibrium. Figure 1 plots schematically the free energy versus temperature $G(T)$ of two contacting phases in the neighborhood of a first-order phase transition. Only at the equilibrium point are the Gibbs potentials G_s and G_f equal, but away from equilibrium the potentials are different. The difference ΔG denotes the driving force of crystallization or growth affinity as $\Delta G = G_f - G_s$.

Figure 1. Dependence of free energy G of fluid (f) and solid (s) phases on the temperature T near the thermodynamical equilibrium (e);
ΔG and ΔT denote the driving forces of crystallization and supercooling, respectively

Most crystal growth processes are carried out near equilibrium. Exceptions are vapor growth processes, in particular molecular beam epitaxy, and some techniques involving chemical reactions on the surface of the growing crystal. The driving force for crystallization is usually defined in terms of the free energy released by crystallization. This free energy change ΔG can be related to more easily measured system parameters for supercooled melts, supersaturated solutions, and supersaturated vapors:

1) *Supercooled Melt.* For a melt supercooled by ΔT (at a temperature T_e–ΔT),

$$\Delta G = \Delta H\, \Delta T / T_e \tag{2}$$

where ΔH is the enthalpy released by crystallizing 1 mol of solid and T_e is the temperature at which the solid and liquid are in equilibrium, in this case the melting point. If ΔT is large or ΔH is small, ΔH in Equation (2) must be corrected to allow for the difference in specific heats of the solid and the liquid. Doing this introduces an additional term in ΔT^2 [54, Chap. 3]. Values of ΔT rarely exceed 10 K. Values of $\Delta H/T_e$ usually fall within a range of 10 to 100 J K^{-1} mol^{-1}, and values of ΔT are typically 1 K. Hence, ΔG is about 100 J/mol, and $\Delta G \ll RT$.
For instance, a propagating (111) face of a dislocation-free silicon crystal requires a supercooling of about ΔT = 4 K [64] (maximal 7 K [63]). By inserting this value in Equation (1) together with the material parameters ΔH = 50 kJ mol^{-1} and melting point T_e = 1693 K, a driving force of crystallization at least of ΔG = 118 J mol^{-1} can be deduced.

2) For a *supersaturated solution*

$$\Delta G = n\, RT \ln(1+\Delta c/c_e) \approx n\, RT\, \Delta c/c_e \tag{3}$$

where n is the number of ions formed in the solution by one molecule of the solute, R is the gas constant (8.31441 J mol^{-1} K^{-1}), T is the temperature, and Δc is the amount by which the solute concentration exceeds the equilibrium concentration c_e. The relative supersaturation

$$\sigma = \Delta c/c_e \tag{4}$$

is often used. Typical values of σ are less than 0.1. A driving force of crystallization of about

500 J/mol was found for perfect NaCl crystal growth from aqueous solution [49]. If ΔH is the enthalpy of solution, Equation (2) can also be used to describe growth from a solution cooled by ΔT below its saturation temperature. Some degrees of supercooling were ascertained for the growth of quartz single crystals under hydrothermal conditions [49].

3) For a *supersaturated vapor*

$$\Delta G = RT \ln(1+\Delta p/p_e) \approx RT\,\Delta p/p_e \qquad (5)$$

where Δp is the amount by which the actual partial pressure of the material exceeds the equilibrium value p_e. If ΔH is the enthalpy of vaporization, Equation (2) can be used to express ΔG in terms of cooling the vapor from its equilibrium temperature. Typically $\Delta p/p_e < 0.1$ and ΔG is ca. 1 kJ/mol

The values of T_e, c_e, and p_e are given by the phase diagram which describes equilibria involving pure, unstrained single crystals. To describe the growth of doped or strained crystals, terms involving elastic strain energy must be added [65]. Similarly, any departure from the phase diagram condition (e.g., the application of hydrostatic pressure, electric or magnetic fields) requires minor modifications of the expressions for ΔG. Such effects at most change growth rates by factors of three.

Figure 2. Free energy as a function of position for a simple model of crystal – fluid interface

In the simplest possible free energy–spatial position model of a crystal–fluid interface (Fig. 2), an energy barrier G_I separates the crystal from the fluid. Therefore, the transfer rate from the fluid to the crystal should be proportional to $\exp(-G_I/RT)$, and the rate from crystal to fluid should be proportional to $\exp[-(G_I+\Delta G)/RT]$. Thus, the net rate of transfer to the crystal should depend on $\exp(G_I/RT)\cdot[1-\exp(-\Delta G/RT)]$ which for $\Delta G \ll RT$ reduces to $\Delta G \exp(-G_I/RT)/RT$.

The determination of the concrete value of G_I is somewhat problematical. Approximately it denotes the activation energy for volume diffusion in the fluid phase, that is, viscous flow in the melt (on the order of 5–50 kJ mol^{-1} [66]). At a crystal–solution interface, solvate shells form or disintegrate, and this requires higher activation energies (desolvation or dehydration energy), yielding G_I in aqueous solutions of 50–100 kJ mol^{-1} [49].

2.2. Phase Relations for Major Components

Because crystals are usually grown in near-equilibrium situations, the actual equlibrium states as described by the phase diagrams should serve as a useful guide to the conditions needed. However, drawings lack accuracy and, for exact work, analytical or tabulated numerical data are preferred. In a well-designed crystal growth system, temperatures can be established with errors of less than 1 K; pressures, between 1 and 5 %; and compositions, 0.1 %.

For introductions to the theory of phase diagrams from the point of view of crystal growth, see [59, 67, 68]. Reference [69] gives an excellent account of the determination of phase diagrams. Techniques have since been automated, but the basic problems are unchanged and several researcher's years of work are still required to determine a three-component phase diagram. For further information on the principles involved, see the standard texts [70 – 72]. A literature search is necessary to obtain the latest data on any particular system. A bibliography up to 1956 is given in [73]. Data for many binary systems can be found in [74 – 77]. Oxide systems are covered by [78 – 80]. Reference [81] gives data for glass-containing systems. For data on the solubilities of materials, see [82]. Numerical data for calculation can be obtained from [83, 84], and [85], and from the data banks discussed in Section 1.5. A journal (*Calphad*) is devoted

to phase diagram calculation, and data on actual systems appear in many journals; in particular, diagrams relevant to crystal growth often appear in *Journal of Crystal Growth, Journal of Materials Science, Journal of Solid State Chemistry,* and *Journal of the Electrochemical Society.* The *Phase Diagram Handbook* with its updating service [86] provides contemporary data on binary diagrams.

Figure 4. Pressures in the Cd – Te system near the compound CdTe
The convention X (Y), e.g., Te (CdTe), is used to indicate the partial pressure of material X over material Y. The symbols Te_c and Cd_c refer to the partial pressure of Te and Cd for the congruently vaporizing solid

Figure 5. Liquid compositions in the Fe_2O_3–Y_2O_3–PbO system in equilibrium with the indicated solid phase

Figure 6. Pressure–temperature diagram for water

Figures 3 – 6 show some typical diagrams; data for these are taken largely from the sources listed above or from [87], in which the phase diagrams of electronic materials are discussed. When phase data are vital, a literature search followed by a critical review of the data should be undertaken. Typical differences found thereby are 1 to 10 K for temperatures, 0.1 to 1 % for compositions, and 5 to 15 % for pressures. Selecting "best available" values is not easy: when

many data are available, median values are probably the best choice, and this has been done in Figure 3 – 6.

Figure 3 shows that part of the phase diagram of the system SiO_2–Bi_2O_3 in air, which is of interest for the growth of the material loosely described as $Bi_{12}SiO_{20}$. The solid line gives the composition of the solid, and the broken line gives the composition of the liquid. At any temperature, the liquid represented by a point on the broken curve is in equilibrium with the solid represented by a point on the part of the solid line nearest to it at the same temperature. The diagram illustrates the wide range of compositions that exist for compounds usually assumed to have a constant composition.

When the growth takes place in pure oxygen, the curves are shifted to the left and the maximum melting point occurs at $x = 11.6$. In argon + 0.5 % oxygen, the curves are shifted to the right and the maximum melting point is at $x = 12.0$.

The formula can differ quite significantly from the idealized value, and at any temperature below the maximum melting point, only two solid compositions can be in equilibrium with a melt.

Figure 4 gives data about vapor pressures of interest in the growth of CdTe. When this formula is written in the form $CdTe_y$, the maximum deviation y lies at 850 °C between about $1 - (1 \times 10^{-4})$ and $1 + (3 \times 10^{-4})$, with a value of $1 + (1.5 \times 10^{-5})$ at the maximum melting point (1092 °C) [88, 89]. Large changes in partial pressures are seen to result from these small changes in composition. The dotted lines represent roughly the partial pressures in equilibrium with the solid which evaporates to give a vapor with the same composition as the solid (called the congruently subliming solid). The distance between the lines has been exaggerated by a factor of about 10^4 to emphasize that they are not equal.

At any temperature, the product $p_{\mathrm{Cd}} p_{Te}^{1/2}$ is a constant. When this condition is observed by annealing at appropriate partial pressures, any composition between the extremes at that temperature can be obtained, but again, only the extreme values can be in equilibrium with a melt.

Figure 5 shows liquid compositions in the system Fe_2O_3–Y_2O_3–PbO which are in equilibrium with the solids indicated in the regions separated by bold lines, the so-called primary crystallization field. The arrows indicate how the molar fractions Fe_2O_3, Y_2O_3, and PbO are represented. For the point shown, the values are 0.50, 0.32, and 0.18, respectively. The broken lines are isotherms. The diagram indicates that, for example, if a liquid containing 50 mol % Fe_2O_3 and 7 mol % Y_2O_3 is cooled from about 1300 °C, the garnet phase should be precipitated. The crystalization field of $Y_3Fe_5O_{12}$ (YIG) is enlarged by the addition of B_2O_3 and PbF_2 to the flux discussed above [90].

Figure 6 shows the phase diagram of water, which is important for hydrothermal growth (Section 7.6). Many other diagrams are of interest to crystal growers; for example, plots of solubility against temperature, which over small ranges can usually be represented as a straight line when the logarithm of solubility is plotted against reciprocal absolute temperature.

2.3. Phase Relations for Minor Components

Usually, the crystal being grown, even if it is a compound, is regarded as contributing one component in a phase diagram and the solute another. Thus, in growing a doped crystal from the melt, the system can be considered a binary one. Similarly in solution growth, three components — the solvent, the crystallizing material, and the solute — are being considered. Because only dilute solid solutions are under consideration, to a first approximation, effects resulting from the concentration of the solute (dopant, impurity) can be neglected, and in equilibrium, is

$$x_{\mathrm{c}} = x_{\mathrm{N}} \exp \frac{-\Delta\mu}{kT} \tag{6}$$

where k is the Boltzmann constant, x_{c} is the atom fraction of the solute in the crystal, and x_{N} is the concentration in the nutrient phase. The parameter $\Delta\mu$ is the chemical potential difference between a solute atom in the crystal and one in the nutrient phase. This difference is almost always positive: it is more difficult to fit a foreign atom into a crystal than into the nutrient (which is usually a fluid). Thus, the segregation coefficient of a solute

$$k_0 = x_{\mathrm{c}}/x_{\mathrm{N}} \tag{7}$$

is usually less than unity. In the general case, $k_0 < 0.1$, but there are many exceptions. It is often

possible to use μ per mole and to replace k in Equation (6 by R (the gas constant).

It is possible to derive Equation (6) rigorously and to show in an ideal case of melt growth that

$$\Delta\mu = \Delta H_2\,(1-T/T_2) - \Delta H_1\,(1-T/T_1) \tag{8}$$

where ΔH_2 is the latent heat of fusion of the crystal which melts at T_2 and ΔH_1 is the latent heat of fusion of the solute which melts at T_1. However, few cases are ideal and it is usually necessary to add extra terms to $\Delta\mu$ which imply the attractive or repulsive forces between the crystal and the solvent atoms, that is, the activities in the solid and fluid phases. For a discussion of these, see [49, 54, 59, 71, 91].

2.4. Interfacial Effects

The surface of a crystal is a gross discontinuity and has a free energy associated with it. The value of this free energy depends on the orientation of the face and the other phase in contact. In surface studies, this phase is usually a vacuum; in the present case, the other phase is often a liquid; for a discussion of crystal–liquid interfaces, see [87]. As a first approximation, the surface free energy is

$$\gamma_{\mathrm{SP}} = (1-w/u)\,\Delta H_{\mathrm{SP}} N_{\mathrm{A}}^{-1/3} \tag{9}$$

where u is the number of nearest neighbors for an atom inside the crystal and w is the number of nearest neighbors in the crystal for an atom on the surface ($w < u$). N_{A} is the Avogadro number and ΔH_{SP} is the energy required to create 1 mol of crystal from the adjacent phase (i.e., the enthalpy of fusion, solution, or vaporization). A plot of γ_{SP} against face orientation gives minima as shown in Figure 7. The cusp-shaped minima give rise to atomically flat (singular) faces. Faces corresponding to less sharp minima may appear to be flat but are not flat on an atomic scale. Typical minimum values of γ_{SP} at crystal–melt and crystal–vapor interfaces are in the rangs 0.1–1.0 and 1.0–10 J/m^2, respectively. In solutions γ_{SP} is somewhat modified by absorption effects of the solvent atoms or molecules at the growing interface and descreases or increases if the solvent is surface active or passive, respectively [92]. Faces that are not singular are atomically rough. The equilibrium shape of a crystal is bounded by the set of singular faces. Real crystals may show nonsingular faces, particularly those corresponding to nonabrupt minima. In the case of small desorientation (some degree) from the singular plane, stepped (vicinal) faces do appear. They consist of lined up singular terraces with equidistant steps of atomic dimensions. Substrates with such surface morphology are of advantages for epitaxial growth in order to guarantee the continuous layer-by-layer growth mode [51].

Figure 7. Polar diagram (full line) showing the variation of surface free energy with orientation
The broken line gives the shape of the cross section of the crystal

In general, the state of the surface plays an eminent role in advanced epitaxial processes, especially of superthin films and alternating multilayer structures. First the reconstruction of the substrate crystal surface, which causes a reduction in the free surface energy, may influence the nucleation and growth modes of the layer to be grown onto it [91]. Further, very thin films possess de facto the surface features as a whole. Strained structures and atomic ordering effects may appear within few monolayers of multicomponent materials on a misfitting substrate, modifying markedly their physical properties relative to these of the bulk state [93].

2.5. Shortcomings of the Thermodynamic Approach

Equilibrium thermodynamics cannot describe processes involving heat and mass transport. Modeling by use of nonequilibrium thermodynamics (e.g., employing a maximum entropy principle) is possible but difficult. The usual approach is to model the kinetics and transport processes separately and then to combine the results to give a complete description. This approach is adopted here.

3. Growth Kinetics

3.1. Atomic Structure of Growing Interfaces

The central question to be solved by using the kinetic approach is the mechanism by which the fluid atoms enter the crystal interface, i.e., growth mode and velocity on the atomic scale. This first requires the determination of the atomic structure (morphology) of the faces to be grown. At $T = 0$ all faces would to be atomically smooth because all atoms are at the same level. At $T > 0$, however, some atoms can leave the uppermost atomic plane by thermal oscillation, leaving behind vacancies and unsaturated lateral bonds and giving rise to a degree of roughness. Such faces can grow nearly without strain by the so-called normal growth mode because most approaching atoms from the fluid phase can be docked in available vacancies (Section 3.2). With increasing bond strength of a crystalline material, indicated by the enthalpy of crystallization, the less increasing the temperature is able to promote roughening. Perfect faces of such materials (ionic and some covalent crystals), show a marked resistance to growth, which can only be overcame by activating mechanisms such as nucleus generation (Section 3.3).

The criterion for transition between a smooth and a rough surface α_J [94] has the form

$$\alpha_J = \Delta H \cdot w / RTu \tag{10}$$

where ΔH is the enthalpy of crystallization, w is the number of nearest neighbors of an atom on the face, u is the number of nearest neighbors of an atom in the crystal, R is the gas constant, and T is the absolute temperature. $\Delta H/T$ is the entropy of crystallization: $\Delta H/RT$ for melt growth is often roughly a constant for a given class of materials, e.g., about 1 for most metals. If $\alpha_J < 2$ the face is rough. If $\alpha_J > 2$ the face will be smooth like those of oxide crystals with large ΔH, for example. Note that α_J varies with the orientation of the face. This is especially important for crystals for which $\Delta H/RT \approx 2$, like most semiconductors. In such cases, the w/u ratio in Equation (10) decides whether the given interface tends to be rough or smooth. For instance, silicon crystals have both atomically rough and smooth areas at melt temperature; α_J becomes 2.6 and 1.7 for the $\{111\}$ and $\{100\}$ faces, respectively. Due to the smoothness of the $\{111\}$ faces they require a higher driving force of crystallization (i.e., supercooling, see Section 2.1) than the rough $\{100\}$ faces.

On growth from vapor most crystal orientations of silicon (and of most other materials) grow atomically smooth due to the much higher sublimation enthalpy ΔH (ca. 300 kJ/mol at 1000 °C), causing an α_J of 27. Growth from solution is also characterized by the presence of mostly smooth interfaces because of the markedly lower crystallization temperatures, i.e., high values of $\Delta H/RT$ (α_J is 15 for NaCl in aqueous solution at room temperature). The kinetic growth modes of such atomically smooth faces (Sections 3.3 and 3.4) differ from the normal mode of rough faces, discussed in Section 3.2.

Note that the above analysis is somewhat simplified and valid for thermodynamic equilibrium only because the roughness of the face is restricted to the single-layer solid–fluid model. Especially at higher temperatures, however, one has to allow for a smearing-out of the crystal face at an arbitrary depth [95]. A computer simulation shows that in such cases the transition criterion α_J is 3.2 instead of 2. Further, during the growth (i.e., deviation from thermodynamic equilibrium) the surface is exposed to a driving force (Section 2.1) and a term $-\Delta G/RT$ must be added to the α_J factor that decreases its value as a function of the degree of supercooling (supersaturation). In other words, higher values of ΔG can promote nucleation islands, transforming a former equilibrium smooth face into a roughened one named "kinetic roughening" [96].

3.2. Rough Faces

With reference to Figure 2, if a Boltzmann distribution of energies for particles (atoms, molecules) in both the crystal and the nutrient phases is assumed, the particle flows to and from the crystal can be evaluated. The fraction of particles in the nutrient that can cross the barrier into the crystal is given by $\exp[-(\Delta G+G_{\mathrm{I}})/RT]$ and the fraction in the reverse direction is $\exp[-G_{\mathrm{I}}/RT]$. The actual fluxes are given by multiplying these fractions by a rate constant *kT/h*, where *k* is the Boltzmann constant and *h* the Planck constant $\left(k/h = 2.084 \times 10^{10}\mathrm{S}^{-1}\mathrm{K}^{-1}\right)$ and *kT/h* is an approximation to an atomic vibration frequency. If the spacing between layers is λ, then the growth rate on a rough surface is given by

$$f_{\mathrm{R}} = (kT\,\lambda/h) \times \exp(-G_1 R/T)\cdot[1-\exp(-\Delta G/RT)] \tag{11}$$

ΔG has been evaluated in Equations (2) to (5), and in general $\Delta G/RT$ is small. Thus, Equation (11) can be reduced to

$$f_{\mathrm{R}} \approx \frac{\lambda\, k \Delta G}{h\, R} \exp(-G_1/RT) \tag{12}$$

According to [97], the diffusion constant in the nutrient can be written as

$$D_{\mathrm{S}} = \lambda^2\,(k\,T/h)\exp(-G_{\mathrm{N}}/RT) \tag{13}$$

and the final form can be obtained as:

$$f_{\mathrm{R}} \approx \frac{D_{\mathrm{S}}\,\Delta G}{\lambda\, RT} \exp[-(G_{\mathrm{I}}-G_{\mathrm{N}})/RT] \tag{14}$$

Here, in general, D_{S}, G_{I}, or G_{N} are hardly known, but f_{R} is proportional to the supercooling $\Delta T/T$ or the supersaturation, either $\Delta c/c$ or $\Delta p/p$. Equation (14) applies only to systems near equilibrium. In systems remote from equilibrium (e.g., molecular beam growth systems), Equation (11) does not apply, and the incoming and outgoing fluxes must be evaluated in some other way (see, for example, Section 8.2). Many examples of growth following Equation (11) or (14) are known, but care must be exercised in claiming the validity of these demonstrations because an equation of similar form can be obtained by consideration of transport processes (see Section 4.3).

3.3. Perfect Singular Faces

In equilibrium, a perfect singular face is essentially atomically flat. Depositing an atom or molecule on such a face produces a large increase in free energy. However, a cluster of atoms or molecules can be stable on the face, but the probability of depositing a cluster is much lower than the probability of depositing one particle. Thus, the growth rate f_{PS} on a perfect singular face is expected to be smaller than f_{R}, the growth rate on a rough surface.

The size of a stable cluster may be modeled by a cluster in which every atom makes half the bonds it would if it were inside the crystal. For a crystal with a diamond lattice (e.g., germanium or silicon), the critical nucleus is 3 atoms on $\{111\}$, 2 atoms on $\{110\}$, and 1 atom on $\{100\}$. Thus $\{111\}$ and $\{110\}$ are singular faces, whereas $\{100\}$ and all other faces are rough. Hence, at any supercooling, growth rates on $\{100\}$ greatly exceed those on $\{110\}$ which, in turn, exceed those on $\{111\}$.

Neither consideration of bonding nor the use of α_{J} allows calculation of growth rates. To do this, the critical free energy of a nucleus ΔG^*, must be calculated. As a nucleus grows, the free energy rises to ΔG^* and then decreases so that further growth is rapid. In macroscopic terms, the free energy associated with a cylindrical nucleus is

$$\Delta G_{\mathrm{N}} = \gamma_{\mathrm{CN}}^2\,\pi r h - \Delta \mathrm{G}\,\pi r^2 h \tag{15}$$

where γ_{CN} is the surface free energy per unit area, *r* is the radius of the nucleus, and *h* is its height. The first term is the increase in free energy due to the extra surface created by the nucleus. The second term is the decrease in free energy obtained by solidifying some of the nutrient phase. By differentiating Equation (15), the following is obtained:

$$\Delta G^* = \pi h_{\gamma_{\mathrm{CN}}} \tag{16}$$

and the critical nucleus has a radius $\gamma_{\mathrm{CN}}/\Delta G$. The rate of formation of critical nuclei [49, 98], is proportional to $\exp(-\Delta G^*/RT)$ and to f_{R}.

Two limiting cases can be distinguished. The first occurs when the nuclei expand rapidly (see Eqs. 21 and 22), in which case

$$f_{\mathrm{PS}} = h\mathrm{d}\,N/\mathrm{d}t \tag{17}$$

$$= A_2 \exp\left(-B_2/\Delta G\right) \tag{18}$$

where N is the number of nuclei per unit area, and A_2 and B_2 are constants. The second occurs when the nuclei expand slowly, in which case

$$f_{\mathrm{PS}} = \left[h\pi\, f_{\mathrm{R}}^2 \frac{\mathrm{d}N}{\mathrm{d}t}\right]^{1/3} \tag{19}$$

$$= A_3 (T\,\Delta G)^{2/3} \exp\left(-B_3/T\,\Delta G\right) \tag{20}$$

where A_3 and B_3 are constants. The conditions for rapid and slow lateral expansion of the nuclei depend on the size L of the face. Rapid expansion corresponds to

$$h\, f_{\mathrm{R}} \gg L\, f_{\mathrm{PS}} \tag{21}$$

and slow expansion corresponds to

$$h\, f_{\mathrm{R}} \ll L\, f_{\mathrm{PS}} \tag{22}$$

Intermediate cases ($h f_{\mathrm{R}} \approx L f_{\mathrm{PS}}$) are difficult to express in analytical form.

Thae use of macroscopic quantities is reasonable for large nuclei. However, for small nuclei (a few molecules), macroscopic quantities have no meaning. If there are n^* molecules in the critical nucleus, another approach can be used [99 – 102], to show that with rapid spread,

$$f = A_4\, \Delta G^{1+n^*} \tag{23}$$

and with slow spread,

$$f = A_5\, \Delta G^{1+n^*/3} \tag{24}$$

where A_4 and A_5 are constants.

As can be seen from Equations (18)–(24), the nucleation-related growth rate at atomically smooth faces depends exponentially on the driving force of crystallization ΔG. Thus, so-called exponential growth modes occur.

Examples of all four relations have been discussed; e.g., see [54, Chap. 3].

3.4. Imperfect Singular Faces

Imperfect singular faces have permanent steps. However, creation of a permanent step is difficult. Consider an artificial vicinal face, i.e., one composed of shallow steps with wide singular treads and short rough risers. Figure 8 shows a sequence of interface positions for a system in which $f_{\mathrm{R}} = 2 f_{\mathrm{PS}}$. In real cases, f_{R} is expected to exceed f_{PS} by much larger factors. The argument about bonding suggests that atoms depositing in the corners (ledge sites) between the treads and the risers will more easily satisfy the condition to make half the possible bonds, but it is possible to consider lattices in which this condition is not obeyed. For example, if in a simple cubic lattice, the treads are (100) and the risers (010), an isolated atom in the ledge site (Fig. 9 A) will only make 2 of its possible 6 bonds so that, even at ledge sites, nuclei of 2 atoms will be needed. [This, of course, is less than the 4 atoms arranged in a square needed to form the stable nucleus on a perfect (100) plane.] However, if the treads are (100) and the risers are (011), an atom in the ledge site forms 3 bonds (Fig. 9 B) so that multiatom nuclei are not needed.

Figure 8. Sequence of interface shapes on a vicinal face The crystal is at the bottom of the figure and the sequence starts from the bottom

Two mechanisms can produce permanent steps. The first is the existence of *multiple twin planes* (Fig. 10). This is usually undesirable but gives a growth rate

$$f_{\mathrm{T}} = \alpha_{\mathrm{TW}}\, f_{\mathrm{R}} \tag{25}$$

where α_{TW} is the ratio of the twin spacing to the interatomic plane spacing normal to the twin planes.

The other mechanism is the existence of *screw dislocations*. A screw dislocation (Fig. 11) is a defect produced by making a cut part way through a block of crystal and displacing the outside edge of the cut by a distance *b,* the Burgers vector of the dislocation. Addition of another layer of atoms does not destroy the step produced. In a growth situation, a spiral forms, which is centered on the dislocation axis shown by an arrow in Figure 11; viewed from above, the dislocated face exhibits a continuous ledge

Figure 9. Straight ledge (A) and kinked ledge (B)

Figure 10. Twinned growth face

Figure 11. Face intersected by a screw dislocation

as shown in Figure 12. The form of this spiral depends on the symmetry of the crystal lattice. The easiest form to treat is a circular spiral with a radial spacing *S*. It can be shown [54] that

$$S \approx 2_{\gamma_{\mathrm{CN}}} V_{\mathrm{M}} / \Delta G \tag{26}$$

although there is dispute about the numerical factor. The fraction of sites which are ledge sites is

$$\alpha_{\mathrm{L}} = \lambda / 2\pi\, S \tag{27}$$

Hence, assuming that the growth rate is

$$f_{\mathrm{D}} = \alpha_{\mathrm{L}}\, f_{\mathrm{R}} \tag{28}$$

yields

$$f_{\mathrm{D}} = \lambda\, f_{\mathrm{R}}\, \Delta G / 4\pi\, \gamma_{\mathrm{CN}} \tag{29}$$

or

$$f_{\mathrm{D}} = A_6 \Delta G^2 \tag{30}$$

where A_6 is a constant.

Figure 12. Projection of a face cut by a growth spiral

A more refined treatment [102] of the growth via surface diffusion yields

$$f_{\mathrm{D}} = A_7\, \Delta G^2 \tanh\left(B_7 / \Delta G\right) \tag{31}$$

which reduces to the normal growth mode

$$f_{\mathrm{D}} \sim \Delta G \text{ when } \Delta G \to \infty \tag{32}$$

and to the square growth mode

$$f_{\mathrm{D}} \sim \Delta G^2 \text{ when } \Delta G \to 0 \tag{33}$$

When diffusion in the bulk of the nutrient is a significant limitation, CHERNOV shows that

$$f_{\mathrm{D}} = \frac{A_7\, \Delta G^2 \tanh\left(B_7/\Delta G\right)}{c_1 + c_2 \tanh\left(B_7/\Delta G\right)} \tag{34}$$

where c_1 and c_2 are constants for a given system [103]. Further refinements [104] give

$$f_{\mathrm{D}} \sim \Delta G^n \text{ when } \Delta G \to \infty \tag{35}$$

where n = 3/2 or 5/3. However, in the usually important range (ΔG small), the square law relation still holds.

4. Transport Effects

4.1. Transport Processes

Before the atoms (molecules) pass over from a position in the fluid medium, just beyond the crystal–fluid interface, to their place in the crystal face they must be transported in the fluid over macroscopic distances towards the interface. Such mass transport may proceed by diffusion, forced diffusion (electromigration), buoyancy-free convection, surface-tension-driven free convection, and forced convection (rotation, acceleration, vibration). Further, the heat carried by the species on their way to the crystal by conductive and convective transport must be dissipated in the solid phase by thermal conduction and radiation to maintain a stable propagating interface.

The transport can be fast or slow compared to the kinetics of attachment. Then the rate at which a crystal grows is limited by interfacial kinetics (Chap. 3) or by macroscopic transport, respectively.

In many cases, the growth rate of a crystal can be written in the form

$$f = A_8\, \Delta G^M \tag{36}$$

where A_8 is a temperature-dependent parameter and M can take many values: for example, M = 2/3, 1, 4/3, 3/2, 5/3, 2, 7/3, 8/3, 3 would be expected and are found [48, 54]. Larger values of M might be expected, but more rigorous theory suggests that much larger values of M are improbable and a value of 4 seems to be the largest reported.

In Equation (36) the relevant value of ΔG is that at the growth face. Generally, the value of ΔG can be measured or estimated more easily at some point remote from the growth face. Thus, relating the interface value ΔG_{I} to some other value ΔG_{B} in the nutrient phase, presents a problem. The easiest way to do this is by using boundary layer theory as discussed in Section 4.2. To illustrate the approach, it is better to consider a specific variable (i.e., temperature or concentration) rather than the free energy difference which the variable creates.

Figure 13 shows the type of concentration distribution to be expected in a solution growth system. Equation (36) can be rewritten in the form

$$f = A_9 (c_{\mathrm{I}} - c_{\mathrm{E}})^M \tag{37}$$

where A_9 is a constant and c_{I} and c_{E} are the solute concentrations at the growth face and in equilibrium with the crystal. Also

$$c_{\mathrm{I}} = c_{\mathrm{B}} - \int_0^{\infty} \frac{\mathrm{d}c}{\mathrm{d}x} \mathrm{d}x \tag{38}$$

which, from Figure 13, can be expressed in the form

$$c_{\mathrm{I}} = c_{\mathrm{B}} - \delta_{\mathrm{S}} \frac{\mathrm{d}c}{\mathrm{d}x}\Big|_{x=0} \tag{39}$$

This relation defines δ_{S}. For either a solid or a fluid nutrient phase, the flux of solute at x = 0 is

$$J = D_{\mathrm{S}} \frac{\mathrm{d}c}{\mathrm{d}x}\Big|_{x=0} \tag{40}$$

where D_{S} is the diffusion constant of the solute.

If the nutrient is a solid or an unstirred fluid, it can be shown that δ_{S} is an increasing function of time and so is not useful, but for a stirred, fluid nutrient, δ_{S} is often a constant. The rate of growth of the crystal must be

$$f = V_{\mathrm{m}}\, J \tag{41}$$

where V_{m} is the molar volume of the crystal. The rates of growth given by Equations (37) and (41) must be the same; hence,

$$\frac{f\, \delta_{\mathrm{S}}}{V_{\mathrm{m}} D} + \left[\frac{f}{A_9}\right]^{1/M} = c_{\mathrm{B}} - c_{\mathrm{E}} \tag{42}$$

Figure 13. Concentration distribution near a growth face The crystal is in the region $x < 0$

This general relation for growth from solution in a fluid depends only on the assumption that at the growth face, the flow of solute in the fluid is purely diffusive, which is reasonable because the fluid at this location does not move relative to the growth face.

4.2. Boundary Layers

In a stirred fluid, the distributions of velocity v, concentration c, and temperature T near a growth interface often take the form shown in Figure 14, and boundary layers with thicknesses of δ_{v}, δ_{S}, and δ_{T} respectively, can be defined. In general, these layer thicknesses are different. Furthermore, not all authors use the thicknesses defined by Figure 14.

The velocity boundary layer δ_{v} is the most fundamental, and the other two thicknesses are related to this by

$$\delta_{\mathrm{S}} = \delta_v (Sc)^{-n_1} \tag{43}$$

and

$$\delta_T = \delta_v (Pr)^{-n_2} \tag{44}$$

where n_1 and n_2 vary from 1/3 to 1 (see Fig. 15) and the dimensionless numbers Sc and Pr are defined in Table 2, which also defines some other parameters.

Figure 14. Distribution of temperature (T), concentration (c), and velocity (v) near a growth face, and definitions of δ_{S}, δ_T, δ_v and interface values c_{I}, T_{I}, and v_{I}

Table 2. Some dimensionless numbers

Parameter	Symbol	Definition
Prandtl number	Pr	$C\,\eta/K$
Schmidt number	Sc	$\eta/\rho\, D_{\mathrm{s}}$
Reynolds number	Re	$L\,\rho\, v/\eta$
Grashof number (for heat transfer)	Gr	$g\,L^3\,\beta\,\Delta T\,\rho^2/\eta^2$
Grashof number (for mass transfer)	Gr'	$g\,L^3\,\alpha\,\Delta c\,\rho^2/\eta^2$
Rayleigh number (for heat transfer)	Ra	$C\,g\,\beta\,\Delta T L^3/K\,\eta$
Rayleigh number (for mass transfer)	Ra'	$g\,\alpha\,\Delta c\,L^3/D\,\eta$

[a] C = specific heat; η = dynamic viscosity = $\nu\rho$; ν = kinematic viscosity; K = thermal conductivity; D_{s} = diffusion constant; ρ = density; g = acceleration due to gravity; L = typical system dimension; $\beta = (1/\rho)\,\mathrm{d}p/\mathrm{d}T$ = thermal expansivity; $\alpha = (1/\rho)\,\mathrm{d}\rho/\mathrm{d}c$ = solute expansivity; T = temperature; c = concentration; v = velocity. ΔT and Δc are changes of T and c along L.

Figure 14 has some practical consequences for the crystal grower. In liquid metals, with typically low Prandtl numbers ($N = Pr \ll 1$), the thermal boundary layer δ_{T} extends farther into the fluid than the velocity transition region δ_{v} because heat transport by conduction dominates over that by convection. However, in molten oxides and aqueous solutions with typically low thermal conductivity ($Pr > 1$), δ_{v} is somewhat broader than δ_{T}. Whereas in the last case the

temperature distribution in the melt (i.e., temperature gradient near the interface) is markedly influenced by the mass flow mode, in metallic fluids the temperature field introduced by the heating furnace remains largely unaffected by convection. Compared to multicomponent melts (fluxes) with Schmidt numbers $N = Sc$ of 10 and higher, this value for gases ranges between 0.1 and 1. Thus, in gases δ_c and δ_v extend about the same distance. In liquids, however, δ_v exceeds δ_c considerably, and therefore in front of the interface, the region of major concentration change, the flow velocity is reduced to relatively small values that barely influence the concentration profile.

Figure 15. Variation of δ/δ_v with N, where $\delta = \delta_T$, when $N = Pr$, and $\delta = \delta_s$ when $N = Sc$
The data are for a rotating disk but should be approximately valid in most situations. For $N \leq 0.05$, $\delta/\delta_v = 0.701\, N^{-1}$. For $N \geq 200$, $\delta/\delta_v = 1.00\, N^{-1/3}$. For $N = 0.1, 0.2, 0.5, 1, 2, 5, 10, 20, 50$, and 100, values of δ/δ_v are 8.06, 4.77, 2.42, 1.56, 1.08, 0.725, 0.546, 0.415, 0.291, and 0.229, respectively. Adapted from [108].

Boundary layer theory cannot be applied indiscriminately. A boundary layer model can only be valid if

1) the Reynolds number

$$Re = Lv/\nu > 1 \tag{45}$$

where L is a dimension of the growth face and v is the velocity of the face relative to the bulk of the fluid which has a kinematic viscosity ν;
2) the dimension of the system normal to the growth face greatly exceeds δ_v; here "greatly" implies a factor of about 5; and
3) the Reynolds number in Equation (45) is such that the flow does not become turbulent. The upper limiting Reynolds number for a rotating disk is about 2000 and for flow along a flat plate about 5000.

A variety of methods are used for stirring in crystal growth systems (Fig. 16) and under further developments (see, e.g., [105 – 107]). These and many other techniques can be described in terms of the following models.

Figure 16. Methods of stirring used in crystal growth
A) Rotation of a pulled crystal; B) Accelerated crucible rotation technique (ACRT); C) Vibration of a plate; D) Reversed rotation; E) Natural convection; F) Forced convection (ω = rotational frequency; n = linear frequency)

Rotating Disk or Cone. For an infinite disk rotating at a rate ω relative to a semi-infinite fluid with the disk on the fluid surface

$$\delta_v = 1.613\,(\nu/\omega)^{1/2} \tag{46}$$

where $\nu = \eta/\rho$ is the kinematic viscosity. The model fits reasonably well, but an error will gen-

erally be introduced by using Equation (46) for a finite disk. Figure 17 gives experimental data for pulled germanium crystals rotated at 90 rpm, which suggest 10 % radial variations in δ_T for a finite crystal with an essentially flat face. For a cone with an included angle 2 θ, δ_v is given by Equation (46) if ω is replaced by $\omega \sin \theta$.

Figure 17. Thickness of a thermal boundary layer relative to the value on the rotation axis as a function of radial position

Figure 18. Value of δ_v on a wedge
Note that the origin of x is the point on the wedge furthest to the left. For $\theta \leq 90°$, the origin is the apex. For $\theta \leq 0$, the boundary layer is on the trailing face. For $\theta \geq 90°$, the boundary layer is that within a concave wedge; as $\theta \to 180°$, δ_v tends to the depth of the re-entrant face. Note that x is measured parallel to the flow

Wedge or Plate. Figure 18 gives δ_v for a wedge with included angle 2 θ in a flow with a relative velocity v. The value for a plate (v is the denominator)

$$\delta_v = 2.93\,(\nu x/v)^{1/2} \tag{47}$$

is obtained by making $\theta = 0$. The layer thickness varies with position (x) except for the case $\theta = 90°$; $\theta > 90°$ corresponds to a concave apex, and $\theta < 0$ corresponds to a wedge facing downstream. For $\theta < -17.9°$, the flow breaks away from the surface (i.e., $\delta_v \to \infty$).

Plate Vibrating in Its Plane. A plate vibrating in its plane at n Hz gives a boundary layer with

$$\delta_v = (2\nu/n)^{1/2} \tag{48}$$

but produces appreciable stirring only in a layer with thickness about 2.2 $(\nu/n)^{1/2}$.

Convectively Driven Flow. Convection may occur when there is an adverse density gradient in the fluid phase. Here, adverse is taken to mean that the density increases upwards vertically or in any direction horizontally. This gradient might be caused by a temperature gradient giving the commonly occurring thermal convection. However, growth can also cause density gradients which may give rise to convection. Any horizontal gradient appears to cause convection, but a vertical gradient seems to cause convection only when the Rayleigh number (either Ra or Ra', Table 2) exceeds some critical value which is typically in the range 1000–2000 for systems with low aspect ration h/D with h the height and D the diameter of the melt column. In the case of increasing melt height, like in full-charged Czochralski crucibles or vertical Bridgman containers, the critical Rayleigh value may increase drastically of some orders of magnitude [59]. In fluids with horizontal temperature or solution gradients (e.g., horizontal-boat crystallization techniques), where the Grashof numbers are more representative, even a threshold-free natural convection can take place [59]. If the velocity v of the convective flow is known, δ_v can be deduced from the data given for wedges or plates. Computer programs and experimental models are available for calculation and observation of

v in most crystal growth arrangements (e.g., [109 – 113]). In principle v varies as L^n, where L is the system dimension in the direction of the gradient and $n = 0.5$.

Accelerated Crucible Rotation. Consider the system shown in Figure 16 B rotating at ω radians per second. If a change $\Delta\omega$ is imposed, radial and vertical flows are initiated and these give a boundary layer with a thickness

$$\delta_v = (\nu/\Delta\omega)^{1/2} \tag{49}$$

which is established in a time of order $\Delta\omega^{-1}$ and which decays with a time constant of about

$$\tau = \left[\nu\left(0.618/H^2 + 14.7/A^2\right)\right]^{-1} \tag{50}$$

where H is the depth of the fluid and A is its radius. This method of stirring (the accelerated crucible rotation technique, ACRT [114]) is useful because stirring is induced without a mechanical connection to the inside of the crucible, but changes in the rotation rate at intervals of less than τ are required. In a time t, the velocity distribution change only extends to a distance of approximately

$$h = t\,(\Delta\omega\,\nu)^{1/2} \tag{51}$$

from the growth face.

Nonsteady Magnetic Field. There are various possibilities of arrangement of time-dependent magnetic fields in melt growth systems–rotating, travelling (down- or upward), and alternating (pulsed). Rotating field, causing a torque in the liquid $\tau_{\mathrm{M}}(B^2, \omega_{\mathrm{M}})$, with magnetic induction B and rotating field frequency ω_{M}, can be used for effective promotion of convective flows in electrically conducting melts [115, 116] Traveling and alternating fields can be applied for damping of the convection streams and control of the morphology of the propagating phase boundary [117 – 121]. Nonsteady fields are generated by using certain electromagnetic coil configurations surrounding the melt zone. Then the velocity boundary layer thickness δ_v decreases according to

$$\delta_v \sim \mathrm{e}^{-\tau_{\mathrm{M}}}\left(B^2, \omega_{\mathrm{M}}\right) \tag{51a}$$

This concept, well known from metal casting, has been revived for the melt growth of semiconductors, especially by zone melting, to homogenize the composition and to damp temperature fluctuations by means of well-controlled forced convection. Only very low values of B (a few mT) are necessary for an effective action [122]. For more information, see also [123 – 125].

4.3. Mass Flow of Major Components

In an idealized melt growth system, the composition of the solid with respect to major components is the same as the composition of the melt, and consideration of the mass flows of major components is rarely necessary: the systems can usually be described completely by considering only heat flow (see Section 4.5). In the case of growth of compounds, minor differences usually exist between the compositions of the solid and the melt (i.e., growth near, but not exactly at the maximum melting composition); however, the defect or excess quantities of the components are small and can be treated as impurities by the methods discussed in Section 4.4.

In growth by evaporative methods (e.g., molecular beam epitaxy), the fluxes of the major components can be calculated directly from the parameters of the source and its distance from the growth face (see Sections 8.1 and 8.2).

Strickly speaking, due to the mass balance at the growth interface, i.e., equality of the fluid influxes $j_{\mathrm{f}} = \rho_{\mathrm{f}}\ v_{\mathrm{f}}$ and solid outfluxes $j_{\mathrm{s}} = \rho_{\mathrm{s}} v_{\mathrm{s}}$ (ρ = mass density), the mass transport rate in the fluid perpenticular to the interface v_{f} is related to the incorporation rate in the solid v_{s} by the density ratio $\rho_{\mathrm{s}}/\rho_{\mathrm{f}}$ as

$$v_{\mathrm{f}} = (\rho_{\mathrm{s}}/\rho_{\mathrm{f}})\, v_{\mathrm{s}} \tag{51b}$$

and may, therefore, differ if $\rho_{\mathrm{s}} \neq \rho_{\mathrm{f}}$ leading to a decelerating or accelerating mass flow of the major component in the fluid if ρ_{s} is less or greater than ρ_{f}, respectively. At the melt–solid transition this difference is small ($\rho_{\mathrm{s}} \approx \rho_{\mathrm{f}}$) and the above approximation is valid. In vapor growth systems, however, where $\rho_{\mathrm{s}}/\rho_{\mathrm{f}} \approx 10^3$, a pronounced fluid mass flow of the major component, the so-called advection or Stefan flow, can be induced [4, 59].

In growth from a solid phase (Chap. 9), the two solid phases are usually assumed to have the same composition with respect to major components (and, indeed, often minor components).

4.4. Mass Flow of Minor Components

Figure 19 shows the distribution of a solute near the growth interface for the usual case ($k < 1$) and for $k > 1$, which is unusual but does occur. Two segregation coefficients can be defined:

1) the interface segregation coefficient (for definition of symbols, see Fig. 19)

$$k_{\mathrm{I}} = c_{\mathrm{S}}/c_{\mathrm{I}} \tag{52}$$

which can sometimes be made equal to k_0 (the value deduced from the phase diagram) and

2) the effective segregation coefficient

$$k_{\mathrm{eff}} = c_{\mathrm{S}}/c_{\mathrm{BN}} \tag{53}$$

As is shown in Section 2.1, a propagating interface requires a certain deviation from thermodynamic equilibrium. The incorporation of minor components is also controlled by atomic processes. To account for this, a kinetic segregation coefficient k_{i} is often introduced. Its derivation, however, is somewhat problematical because of the actual concentration c_{I} immediately at the interface is unknown (see Fig. 13). Different theoretical approaches to the formulation of k_{i}, especially in the case of atomically smooth faces, are presented in [4, 49], for example. In general, for growth from a melt involving atomically rough interfaces and near-equilibrium conditions, k_{i} equals k_{I}, and the above equations are justified.

For a macroscopically flat growth interface, a one-dimensional equation

$$D_{\mathrm{S}}\frac{\partial^2 c}{\partial x^2} + f\,\frac{\partial c}{\partial x} = \frac{\partial c}{\partial t} \tag{54}$$

can be solved with the boundary condition

$$D_{\mathrm{S}}\frac{\partial c}{\partial x}\Big|_{x=0} = c_{\mathrm{I}}\,(1-k_{\mathrm{I}})\,f = D_{\mathrm{S}}\,(c_{\mathrm{I}}-c_{\mathrm{BN}})\,/\Delta_{\mathrm{S}} \tag{55}$$

In a steady state, $\partial c/\partial t = 0$ and the solution is [33, 34]

$$k_{\mathrm{eff}} = \frac{k_{\mathrm{I}}}{k_{\mathrm{I}} + (1-k_{\mathrm{I}})\exp\left(-f\,\delta_{\mathrm{S}}/D_{\mathrm{S}}\right)} \tag{56}$$

which, for small values of $f\,\delta_{\mathrm{S}}/D_{\mathrm{S}}$, reduces to

$$k_{\mathrm{eff}} = \frac{k_{\mathrm{I}}}{1-f\,\delta\,(1-k_{\mathrm{I}})\,/D_{\mathrm{S}}} \tag{57}$$

Figure 19. Concentrations of a minor component near a growth face for $k < 1$ (A) and $k > 1$ (B)

These relations have been repeatedly verified and shown to be excellent approximations, provided that δ_{S} is calculated by using Figure 15 rather than one of the limiting formulas and that there is no growth-induced flow. Thus, for example, Equation (54) applies for melt growth if the densities of the solid and liquid are identical. If this condition is not obeyed, then f must be replaced by a parameter $f^* = (1+\Delta)\,f$, where Δ is a constant for the particular system and f^* is the growth rate measured relative to fluid particles near the growth face (i.e., roughly at $x = \delta_{\mathrm{S}}$).

It is permissible to assume that $\partial c/\partial t = 0$ if changes occur at rates that are slow compared to the time (roughly $\Delta_{\mathrm{S}}^2/D_{\mathrm{S}}$) needed to modify the solute distribution in the boundary layer.

This time is usually less than one second so that Equation (54) is generally valid and may be used to describe the effects of changing either the growth rate or the boundary layer thickness δ_S. Such changes can obviously occur as a result of apparatus imperfections which can be mechanical (changes in rotation rates, etc.) or thermal (lack of perfection in temperature control). However, the most intractable problems are caused by thermal oscillations. These are time-dependent variations in the convection currents in the system, which occur in particular ranges of the Rayleigh numbers *Ra* and *Ra′* [59, 111]. Because the Rayleigh numbers depend on L^3 (Table 2), large fluid volumes are more prone to thermal oscillations than small ones and the occurrence of thermal oscillations provides a major limitation on the size of crystal growth systems. The obvious methods of minimizing the problem are (1) to work with minimal density gradients (e.g., keep temperature gradients small), (2) to design the apparatus to have effectively small dimensions (e.g., add baffles, which can be porous), and (3) to maximize viscosity (for conductive fluids, this can be achieved by applying a magnetic field [95]). The critical values of *Ra* and *Ra′* are usually several times the value needed to initiate convection (say > 2500). For *Ra* or *Ra′* greater than this value, both the oscillation amplitude and its frequency increase with *Ra* or *Ra′*.

4.5. Heat Flow

Crystal growth is always accompanied by a latent heat (the enthalpy of crystallization ΔH_C). In most cases, ΔH_C is positive (i.e., heat is evolved), but in a few instances, heat is absorbed, for example, the growth of lithium sulfate from solution in water.

If the subscripts S and N are used to denote the crystal and the nutrient phases, then at any plane growth face in a steady state:

$$K_N \frac{dT_N}{dx}|_{x=0} + \frac{\Delta H_C}{V_m} f = K_S \frac{dT_S}{dx}|_{x=0} \tag{58}$$

where K is the thermal conductivity at the temperature T, V_m is the molar volume, f is the growth rate, and x is a coordinate axis normal to the face with $x = 0$ at the face. The term dT_s/dx denotes the axial temperature gradient in the crystal near to the interface. Numerous efforts have been directed at its exact determination in growth experiments in the past. For instance, it was shown analytically, that in cylindrical crystals with high emissivity ε (metals, semiconductors) pulled from melts (Section 6.1) at high temperatures (> 1000 °C), the dissipation of the heat is dominated by radiation from the crystal surface, and dT_s/dx equals in good approximation $\left(\varepsilon\sigma_P T_e^5 a^{-1}\right)^{1/2}$, where σ_P is Planck's constant, T_e the melt temperature, and a the crystal radius. Computer calculations, including enthalpy of crystallization, thermal conductivity, convection in the fluid phase, and radiation processes, can provide almost realistic knowledge on the course of steady and nonsteady temperature fields in growing crystals ([110, 111], for example). Nowadays, even convective processes such as turbulences in the gas phase within the growth chamber are being included in the models [126].

If the nutrient is a stirred fluid, the first term is $K_N\left(T_{BN} - T_I\right)/\Delta T$ (see Fig. 14). In melt growth, if T_{BN} varies by ΔT at a rate which is slow compared with the response times of the boundary layer $\left(\Delta T^2/\varkappa_N\right)$ and the crystal $(a^2/\varkappa_S)$, then the growth rate changes by

$$\Delta f = (K_N V_m/\Delta H_C)\,(\Delta T_N/\Delta T_S) \tag{59}$$

where $\varkappa$ is the thermal diffusivity ($K/C\rho$) and a is the radius of the crystal. The change ΔT can be caused by a thermal function of the control system or by thermal oscillations. To evaluate the effect of ΔT on the concentration of a solute, $\partial k_{eff}/\partial f$ is calculated from Equation (54) and multiplied by Δf. In solution growth or other methods, the same ideas are used, but the dependence of growth rate on the interface temperature is a complicating factor. (In melt growth, the interface temperature can be regarded as a constant. This is not the case in any other method of growth.)

Dislocations. Uniform heat flow in a growing crystal has no significant effect. A nonuniform flow promotes the dislocation multiplication due to thermomechanical stress such as edge dislocations (Fig. 20). Consider a rod-shaped crystal growing in the z direction with a plane growth face at $z = 0$ and a radius a. The temperature distribution is given by

$$\frac{\partial T}{\partial t}+f\,\frac{\partial T}{\partial z}-\kappa\nabla^2 T=0 \tag{60}$$

where f is the growth rate and κ is the thermal diffusivity. It is assumed that the growth face is the isotherm $T = T_{\mathrm{I}}$ and that heat is lost from the curved surface at a rate $h\,(T–T_0)$, where h is the heat transfer coefficient. Then, provided the crystal is fairly long (say 6 a, although the solution for shorter crystals is known):

$$T-T_0\approx\frac{(T_{\mathrm{I}}-T_0)\left(1-h\,r^2/2\,a\right)}{(1-h\,a/2)}\cdot\exp\left[-\left(\frac{2\,h}{a}\right)^{1/2}z\right] \tag{61}$$

and

$$\frac{\partial T}{\partial r}\approx-\frac{(T_{\mathrm{I}}-T_0)}{(1-h\,a/2)}\,\frac{r}{a}\exp\left[-\left(\frac{2h}{a}\right)^{1/2}z\right] \tag{62}$$

When circles of constant r are considered, it can be seen that this radial gradient will give rise to hoop stresses and if the material is plastic, it will at some magnitude of hoop stress, deform to give dislocations. (If the material is brittle, it will crack at a critical hoop stress.) If τ_{C} is the critical shear stress for plastic deformation and G is the shear modulus, then the dislocation density is

$$N_{\mathrm{d}}=\frac{\alpha}{b}\,\frac{\partial T}{\partial r}-\frac{\pi_{\mathrm{C}}}{G\,ba} \tag{63}$$

where α is the coefficient of thermal expansion. For

$$\frac{\partial T}{\partial r}<\frac{\tau_{\mathrm{C}}}{G\,\alpha\,a} \tag{64}$$

dislocation-free growth is possible. Typically $\tau_{\mathrm{C}}/G\approx10^{-3}$ and $\alpha\approx10^{-5}\ \mathrm{K}^{-1}$ so that if a is measured in centimeters, the critical value of $\partial T/\partial r\approx100/a$ K/cm.

Also the axial temperature distribution in a crystal may create similar magnitudes of stress to the curvature of the isotherms in the radial direction. It was demonstrated by the thermoelastic theory of dislocation generation [127] that nonlinearities of temperature gradients (second derivations) are the sources of stress. Due to the extremely extensive numerical calculations the following relation is helpful in estimating the stress σ in the region behind the growth interface

$$\sigma\approx\alpha\,E\,L^2\partial^2T/\partial z^2 \tag{64a}$$

where E is the elastic modulus and L the characteristic axial length, which is on the order of 20 % of the crystal diameter. Conclusions can then be made about the dislocation density by comparing σ and τ_{c}; no dislocations are generated if $\sigma<\tau_{\mathrm{c}}$. In semiconductors τ_{c} is in the region of 0.7 (GaAs) to 9 MPa (Si), hence, under similar thermal conditions, dislocation-flawed GaAs and dislocation-free Si crystals are grown. Two-dimensional maps of computer-simulated temperature and stress fields in the growing crystal are now routinely plotted [110].

The local dislocation density can be estimated theoretically from the constitutive law linking the plastic shear rate and dislocation density with the applied stress in the course of the cooling-down procedure of the crystal

$$d\varepsilon/dt=\tau bV_o(\tau_{app}-D\sqrt{\tau})^m\cdot\exp\left(-\frac{Q}{kT}\right)$$

where ρ is the density of moving dislocations, b the Burgers vector, V_o a pre-exponential factor, m is a material constant, Q the Peierls potential, D a parameter relating ρ and τ, and τ_{app} is the applied stress. Details of this approach can be found in the profound review [128].

Today, the global numeric modeling of the non-stationary elastic stress and related dislocation development in growing crystals is used by implying the history of the thermal field in the furnace and crystal as well as the convection in the melt and vapour phase [129].

Figure 20. An edge dislocation (arrow)
The broken lines are the intersections of atomic planes with the faces of the crystal. The dislocation axis shown by the arrow is at right angles to the Burger's vector b, which, in this example, is one interplanar spacing

Thermal stresses are not the only source of dislocations; in particular, dislocations in the seed crystal usually propagate into the growing crystal and can nucleate at inclusions in the crystal. Further details and an approach to the dynamic dislocation theory, which considers interactions between dislocations already existing in the crystal during the cooling down process, are given in [128].

4.6. Interface Stability

In Chapter 3, the growth rate f was shown to be an increasing function of ΔG. Thus, if ΔG increases away from a growth face (as, for example, is always the case in solution growth), a projection on the growth face caused by a fluctuation in the growth process may grow more rapidly than the remainder of the face, and the face is unstable. When this happens, the liquid is said to be constitutionally supersaturated (if the instability results from a concentration gradient), constitutionally supercooled (if the instability results from the combination of a concentration and a temperature gradient), or thermally unstable (when a temperature gradient is the sole cause).

Thermal instability can only arise in melt growth. The condition for thermal instability can be derived from Equation (56) and the condition that $\mathrm{d}T_\mathrm{N}/\mathrm{d}x < 0$ (where x is measured normal to the growth face), which together yield an instability condition

$$K_\mathrm{S}\frac{\mathrm{d}T_\mathrm{S}}{\mathrm{d}x}|_{x=0} - \frac{\Delta H_\mathrm{C}\, f}{V_\mathrm{m}} < 0 \tag{65}$$

Elimination of the instability involves practical steps to increase the first term or decrease the second term on the left-hand side of this relation.

The instability condition for constitutional supercooling can be shown to be approximately [130, 131]

$$\frac{\mathrm{d}T_\mathrm{S}}{\mathrm{d}x}|_{x=0} < mc_\mathrm{BN}\ (1-k_\mathrm{I})\ f\, k_\mathrm{eff}/k_\mathrm{I}\, D_\mathrm{S} \tag{66}$$

where c_BN is the concentration of the dopant with distribution coefficients k_I and k_eff and a diffusion coefficient D_S. The parameter m is the slope of the liquidus (i.e., $\partial T_\mathrm{E}/\partial c_\mathrm{BN}$), where T_E is the equilibrium temperature on the phase diagram.

The effective segregation coefficient k_eff represents the influence of melt convection. In the case of complete mixing ($f\delta_\mathrm{s}/D_\mathrm{s} \ll 1$), Equation (54) becomes $k_\mathrm{eff} = k$, and only a small temperature gradient has to be established for preservation of interface stability (if $k < 1$). In motionless melts, $k_\mathrm{eff} = 1$, and this represents the highest danger of instability. Hence, convection may stabilize growing interfaces against morphological instability.

The instability condition for constitutional supersaturation can be shown to be

$$f > \frac{V_\mathrm{m} D_\mathrm{S} c_\mathrm{E}}{T}\,\frac{\partial T_\mathrm{N}}{\partial x} \cdot \left[\frac{c\Delta H_\mathrm{C}}{c_\mathrm{E} RT} - \frac{T\,\partial f/\partial T}{\partial f/\partial\{(c-c_\mathrm{E})/c_\mathrm{E}\}}\right] \tag{67}$$

which points to the role of the temperature gradient in solution growth.

The conditions given above are approximations that ignore some stabilizing forces. In particular, a face growing by nucleation with rapid spread will always be stable and the stabilizing effect of the surface free energy has been ignored. Thus, faces are usually more stable than these relations suggest. For further discussion of stability relations, see [48, 57, 59, 132].

Even if a face is potentially unstable, there is no certainty that the instability will develop. A suitable fluctuation is necessary to initiate unstable growth and it takes time for the instability to develop. For example, in thin-layer growth instabilities are rarely seen, even in systems which must be potentially unstable. However, interface instability does provide a real limit to the maximum obtainable growth rate and, at a given growth rate, to the maximum size of a growth face. (Remember that the maximum value of $\mathrm{d}T_\mathrm{S}/\mathrm{d}x$ falls with face size.)

5. Practical Considerations

5.1. Raw Materials

Many materials with fewer than 10 ppm of impurities are now available. Used with care, such materials yield crystals with about 1 ppm of impurity. Most crystal growers buy their raw materials from specialist suppliers, who supply various grades. Typically, the price paid doubles for each factor of ten reduction in impurity content. Purification is sometimes necessary; thus, most organizations using water as a solvent purify

their own water. A process sequence of filtering, reverse osmosis, deionization, and ultrafiltration is typical. In other cases, raw materials may be transferred to the growth system by distillation, which typically removes more than 90 % of the impurities present. When uncommon materials are required, in-house processes become essential, and crystal growth groups often distill or zone refine some of their raw materials.

5.2. Temperature Control

Spatial variations (temperature distribution) involve both uniformity and controlled nonuniformity. To produce regions with low temperature gradients requires the use of structural components with large effective thermal conductivities. At the lowest temperatures employed for crystal growth, stirred fluid baths are widely used. For higher temperatures (over 100 °C), metals (e.g., aluminum up to about 500 °C, copper to somewhat higher temperatures, and various steels up to about 1200 °C) can be useful. Above about 400 °C, liquid-metal filled heat pipes can be helpful, but with a given heat-transfer fluid, the optimum performance of a heat pipe exists only over a small temperature interval. Obtaining desired gradients over limited distances is more difficult than obtaining a uniform temperature. Essentially, the problem is one of the heat flow that must accompany the gradient. Structural materials with low thermal conductivities (ceramics, mineral fiber wools, and even evacuated spaces) can play a part, but heat transfer in nutrient materials (particularly fluids) and in the crystals being grown can be significant, and considerable ingenuity may be needed to obtain the desired distribution without producing radial gradients that are harmful to the crystal (Section 4.5).

Fully computer controlled heating systems, consisting of cylindrical multizone side heaters and top and bottom heaters, surrounded by insulating materials, are today of increasing interest due to their ability to realize nearly uniaxial heat flow through the growing crystal [133]. Excellent insulative properties are exhibited by modern carbon materials composed of interpenetrating layers of carbon fibers (calcarb). The very good machinability, low thermal conductivity (ca. 10^{-6} K^{-1}), and high temperature stability up to 2000 °C and above make this material very suitable for numerous high-temperature crystal growth processes that require minimal radial temperature gradients.

The availability of sensitive temperature transducers (thermocouples, resistance thermometers, and radiation sensors) together with solid-state temperature controllers has greatly simplified the designer's problems. However, the targets to be reached have also become more difficult: it is now common to demand temperatures of 1000 °C with variations of less than about 0.1 °C, and in the range 40–100 °C variations of less than 0.01 °C are often requested. The state of the art allows a tenfold improvement on these figures by use of multistage processes.

5.3. Containers and Atmospheres

Both the crystal and the nutrient from which it is growing must be in contact directly or indirectly with some solid part of the growth apparatus, and both may be in contact with an atmosphere. Thus, surface contamination and some contamination of the bulk materials, particularly in the slower growth processes, are expected, because most crystal growth processes occur at elevated temperature.

Solids in contact with the crystal and the nutrient must be selected with care. Graphite is a widely used material which is stable in contact with many solid and liquid halides and semiconductors (however, not with silicon), but reacts with many oxides. Silica (vitreous SiO_2) is used extensively but reacts slowly with molten silicon. Glasses, particularly borosilicates, are used widely, but care must be exercised because some components can be leached preferentially. The platinum metals, particularly platinum and iridium, are useful for work with oxides and halides.

For the growth of semiconductor compounds such as GaAs, InP, and GaP, pyrolytic boron nitride (pBN) has became the most widely accepted crucible and container material because of its high purity, thermal stability (up to 3000 °C in inert gas atmosphere), low outgasing, and nonwetting characteristics. In particular, using pBN as alternative to quartz in Czochralski and Bridgman growth methods (Sections 6.1 and 6.2) eliminated the problem of silicon contamination, and the semi-insulating

behavior of GaAs became apparent in production. pBN is also the most widely utilized container material for MBE sources. For HF induction coupling in the region up to 3000 °C, high-purity glassy carbon ampoules and containers have gained in significance.

In choosing solids for containers, care must be exercised in selecting the grades to be used. Materials which are satisfactory in a pure form may be unsatisfactory in technical grades. For example, pure platinum is a satisfactory container for alkaline molten oxide materials, but technical-grade platinum contains some rhodium which is easily leached out by these oxides.

Figure 21. Impingement rates (molecules per unit area per unit time) as a function of partial pressure for typical residual gases in a vacuum system

Similar care is required in choosing gases for ambients. Water is a common contaminant of gases from cylinders (however, many glasses contain significant amounts of water so that if the absence of water is essential, the correct construction materials must be chosen). Hydrogen is widely used because it can be purified readily by diffusion through heated palladium. Vacuum is commonly thought to be a clean "atmosphere." However, typical vacuum systems contain appreciable amounts of H_2O, CO, CH_4, and hydrogen (which is difficult to pump away). Water and carbon monoxide usually come from films absorbed on the inside walls of the vacuum system, and methane can be formed by the cracking of pump oils. For further information about vacuum technology, see [134]. Figure 21 shows that relatively low partial pressures give rise to appreciable impingement rates so that one monolayer can form in one second with a partial pressure of about 10^{-9} bar. A partial pressure of about 10^{-8} bar gives an impingement rate equivalent to a growth rate of about 1 µm/min so that thin-layer growth from a vapor at 1 µm/min requires partial pressures of about 10^{-14} bar to avoid contamination at a level of about 1 ppm. Pressures of 10^{-13} bar are currently the state of the art. Thus, if all atoms impinging are incorporated, a contamination of about 10 ppm must be expected. Fortunately, most of the impinging atoms are desorbed before they are incorporated, and crystals are usually purer, by a factor of ten or more, than these estimates suggest.

5.4. Selection and Optimization of Methods

Selecting and optimizing methods of growth requires information about the methods available, the nature of the material, and its use. For example, if thin layers are needed, cutting thin sheets from bulk crystals might be very expensive, but in some cases, this may be the only approach; for example, no method for producing the α-quartz needed for resonators in thin-sheet form has yet been found. In fact, only a few, rather limited methods exist (Section 6.1) for making thin, unsupported layers. Most thin-layer growth methods make use of a substrate which cannot be removed easily.

Bulk Crystals. For growing bulk crystals, *melt growth* is likely to be the fastest method (volume per unit equipment time), but it is only applicable to materials that melt congruently and have no destructive phase changes. Also, melt growth involves the highest possible temperatures and, therefore, the maximum possibilities of contamination. Of the available melt growth methods, the Czochralski and floating-zone methods can reliably yield dislocation-free crystals, and the floating zone method can yield large crystals only of materials whose melts have a high ratio of surface tension to density. (Typical ratios are in the range 3 to 300 $cm^2\ s^{-2}$ but only materials with ratios exceeding about 100 $cm^2\ s^{-2}$ are suitable for floating zone refining.)

Due to the marked improvement in container materials (pBN, glassy carbon) and computer-controlled temperature programming, the Bridgman method has achieved a noteworthy renaissance for the relatively cheap production of high-quality crystals with excellent diameter accuracy, and dislocation densities in semiconductor compounds of less than 10^3 cm^{-2} are typical [135]). Skull melting is the cheapest method of melt growth but gives high dislocation densities in irregularly shaped crystals.

Vapor growth techniques probably give the second highest growth rates but are applicable only to materials that are volatile or give rise to reversibly decomposable compounds. Due to the low condensation temperature relative to the melting point, low-temperature single-crystalline phases can be grown directly without passing through harmful solid–solid phase transitions. This phase transition is today more and more used for the growth of materials with high melting point, such as nitrides (GaN, AlN) and silicon carbide, which are of increasing importance for advanced micro- and optoelectronics.

Solution growth techniques are usually the slowest processes and are applicable only to materials that are reversibly soluble.

Solid-phase growth techniques are not used commercially for bulk crystal production because yields are low. All the other methods of growth allow some segregation of impurities so that the crystals can be purer than the starting materials. However, for special materials with high melting points or solid phase transitions, solid-state recrystallization by exploiting the phenomenon of grain growth in thermally stressed polycrystalline samples is under investigation.

Thin Layers. For thin-layer processes, crystals can be grown from solution (liquid-phase epitaxy, LPE), from the vapor (vapor-phase epitaxy, VPE, or molecular beam epitaxy, MBE), or from the solid state (solid-state epitaxy, SSE). In the last case, the solid from which growth takes place is likely to be amorphous. Liquid-phase epitaxy is used quite widely. It is almost the only technique available to make thin layers of garnets for magneto-optic devices (bubble memories, display devices) and for single crystalline phosphors for high-intensity cathode-ray tubes. Liquid-phase epitaxy is also used for semiconductors, where it generally yields layers purer than other methods but usually with rather imperfect surfaces. Molecular beam epitaxy is rather slow but can yield complicated structures with many layers and sharp composition changes; the substrate temperature can be very low, e.g., 100 °C. Vapor-phase epitaxy using halides (VPE, CVD) or organometallic compounds (OMCVD or OMLPE) is widely employed for semiconductors. Recently, SSE has been used for semiconductors, but proper evaluation of this method requires more experience with a wider range of materials. Choosing the optimum thin-film method is particularly dependent on the use. Almost the only general statement that can be made is that MBE is unlikely to be economic for thick layers. However, it plays a leading role in the production of quantum-size devices such as quantum wells, wires, and dots.

Optimization. Method optimization usually implies an increase in scale, such as larger volumes for bulk crystals, or larger areas for thin layers. In general, large crystals have to be grown at slower rates than small ones if perfection and uniformity are to be maintained, and costs do not decrease as rapidly as they would if the rates could be maintained. Nutrient costs do not decrease with crystal size and are typically one-third of total costs. A larger apparatus uses energy more efficiently, but the energy costs are low (usually $< 10\,\%$ of total costs). Equipment and labor costs do not rise linearly with crystal dimensions, so some savings are possible. In general, automation is a paying proposition. The extra cost for equipment is usually less than the savings in labor cost, and automated equipment can produce more uniform material with higher yields than manually controlled equipment. Operator errors can easily result in losses that exceed 20 %.

5.5. Characterization

In general, the number of characterization techniques is vast and rapidly growing, so that only the main essentials can be summarized here. With resepect to crystal growth the various characterization techniques can be roughly grouped into three categories:

1) Characterization of composition and purity

2) Structural characterization
3) Characterization with respect to specific physical properties, depending on special material properties and on the application for which the material is intended

Further, analytical methods can be divided into destructive and nondestructive as well as in-situ and post-growth techniques. The development of suitable in-situ techniques is of major importance for advanced crystal growth. Whereas in the case of thin film growth, especially MBE, the in-situ observation and control of the crystallization modes (by RHEED and scanning tunneling microscopy, for example) is already state-of-the-art [136], for bulk growth from the melt this is an as-yet unresolved problem, primarily because of the lack of adequate sensors and analytical techniques. Considerable progress has been achieved in solution and vapor growth by using laser scattering, especially in holographic mode, for the investigation of diffusion boundary layer thicknesses and growth kinetics.

Today it is important that the experimental analytics are combined with modelling of the observed effects. Modelling includes both the simulation of the solid with its various specific structural features and modelling of the effects exerted by a solid with this structure on the analytical probes. Modelling is also necessary for image enhancement.

Skilled personnel can obtain a great deal of data in a nondestructive mode by just looking at a crystal. Visual inspection directly or by microscope (particularly one with an interference, e.g., Nomarski, lens) reveals surface irregularities on natural faces or other grown surfaces. Networks of grooves suggest low-angle grain boundaries. Isolated straight lines (particularly on lightly abraded faces) suggest twins. Pyramids suggest screw dislocations or stacking faults. Sets of parallel lines suggest concentration striae. On etched surfaces, pits probably indicate dislocations or vacancy clusters. For transparent materials, light-scattering centers in the bulk may be inclusions. Many crystals are transparent in the infrared, and infrared microscopy is a powerful tool. Transparent crystals can also be examined by using polarized light, which readily reveals built-in strains. Such strains, indicating large-scale effects resulting from the simultaneous existence of more than one type of growth face, inclusions or dislocations or internal strain arising from dislocation or impurity distribution, can be revealed by X-ray topography (see, for example, [137]). Similar data can also be obtained by electron microscopy. It is often necessary to know the compositions of crystals, especially the concentrations of deliberately added dopants and accidentally occurring impurities. The spatial variations of composition are also of interest. Thus, it is desirable to find methods which work on small samples. Table 3 gives typical data for the methods commonly used. When the sample size is given as an area times a length, the length is normal to the sample surface. Other methods are less generally used. For further data, see [19, 48, 138, 139].

6. Melt Growth Techniques

6.1. Crystal Pulling

The order of the following sections reflects the amount of use that is made of each method; the Czochralski method is used to a greater extent than the other four techniques.

Czochralski Method. The basic sequence of operations in the Czochralski method is shown in Figure 22. A seed crystal is dipped into the melt, and a small amount of the seed is allowed to melt. Pulling is then begun, and the melt temperature is adjusted so that the first portion grown has a diameter just smaller than that of the seed. For dislocation-free growth, the diameter is then reduced to about 2 mm by raising the melt temperature slightly. This diameter is maintained for about 10 mm and then increased to the final target value (dislocations, except those exactly parallel to the seed axis, grow out while this neck is grown). When dislocation-free growth is not required, the diameter can be increased after the first 2 or 3 mm of growth. Decreasing the melt temperature increases the crystal diameter and vice versa. Increasing the rate of pull or the relative rate of rotation of the crystal decreases the diameter. The word relative is used here because many workers may rotate the seed and the crucible in opposite directions. Some workers also raise the crucible to maintain the liquid surface at the same height relative to the apparatus.

Table 3. Methods for determining composition

	Method	Sample size	Destructive?	Detection limit (atom fraction)
a	Gravimetry	20 mm^3	yes	10^{-5}
b	Titrimetry	10 mm^3	yes	10^{-5}
c	Electro-chemical methods	10 mm^3	yes	10^{-4}
d	Isotope dilution	2 mm^3	yes	10^{-4}
e	Atomic absorption spectrometry	20 mm^3	yes	10^{-7}
f	AAS (with graphite furnace)	2 mm^3	yes	10^{-8}
g	Solid-source mass spectrometry	2 mm^3	yes	10^{-8}
h	Neutron activation	0.2 mm^3	yes	10^{-9}
i	Charged-particle activation	2 $mm^2 \times 100\ \mu m$	yes	10^{-9}
j	X-ray fluorescence	25 $mm^2 \times 20\ \mu m$	no	10^{-5}
k	Rutherford backscattering	1 $mm^2 \times 2\ \mu m$	no	10^{-3}
l	Electron-probe (X-ray spectrum)	4 $\mu m^2 \times 2\ \mu m$	no	10^{-3}
m	Secondary-ion mass spectrometry	0.1 $mm^2 \times 10$ nm	yes	10^{-9}
n	Auger spectrometry	100 $\mu m^2 \times 1$ nm	no	10^{-2}
o	X-ray photo-electron spectrometry	10 $mm^2 \times 1$ nm	no	10^{-3}
p	Low-energy ion scattering	1 $mm^2 \times 1$ nm	no	10^{-4}

Figure 22. Sequence of operations in the Czochralski method

This is particularly convenient when the system for controlling diameter employs the reflection of a light beam on the curved portion of the melt near the edge of the crystal. The other commonly used method of diameter control involves weighing the crystal or the melt.

The rotation and pulling rates used depend on the material being grown and the diameter of the crystal. Larger crystals need slower pulling and rotation. The maximum pulling rate is roughly inversely proportional to the diameter to the power 1.5. Typical rates for 2-cm diameter crystals range from 3 mm/min (silicon and germanium) to 3 mm/h (oxide crystals with low thermal conductivity). Rates as high as 12 mm/min and as low as 1 mm/h have been reported. Crystal rotation rates tend to be proportional to the reciprocal of the crystal diameter. For 2-cm diameter crystals, rates of 5–50 rpm are typical. Crystals of silicon up to 30 cm diameter are pulled (40-cm technology is under development); alkali metal halides can have much larger diameters.

When electrically conducting crucibles are used, power can be supplied by radio-frequency heating as shown in Figure 23, which also illustrates the use of an encapsulant to prevent decomposition of materials with a volatile com-

ponent. When nonconducting crucibles are used, radio-frequency power may be coupled directly to the melt, but more usually a resistive heater coaxial with the crucible is used. Such heating elements can be made from graphite, silicon carbide, or molybdenum or from resistance wires wound on ceramic formers.

Figure 23. Liquid encapsulated growth by the Czochralski technique (LEC)
This method is used to grow a material with a high partial pressure of one or more component. Use of an encapsulant (usually boric oxide, but occasionally a halide), shown dotted, prevents loss of volatile material from the melt and from the crystal if the pressure in the growth chamber exceeds the sum of partial pressures of the components

Usually, the conventional Czochralski technique is characterized by high temperature gradients and thermal nonlinearities in the growing crystal, which are harmful for materials with low critical resolved shear stress (semiconductor compounds). To decrease the temperature gradients, afterheating systems are used. To prevent dissociative decomposition of the hot crystal surface, in such cases, a closed inner growth chamber with a controlled atmosphere of the volatile component can be used [140].

A comprehensive overview on the Czochralski technique is given in [141].

Kyropoulos Method. The Kyropoulos method uses a seed crystal that is dipped into the melt, but growth is maintained by continuously lowering the crucible temperature (Fig. 24). Linear growth rates are low, but the area of the growth face is large so that volume growth rates are reasonable but significantly lower than those obtained by the Czochralski method. The Kyropoulos method is widely used to produce halide crystals for optical components. Crystal diameters and lengths are usually comparable. Crystals with dimensions greater than 50 cm have been grown. The major practical problem appears to be seed breakage. For this reason, seeds and crucible rotations are sometimes not used. Dislocation densities tend to be high ($> 10^4$ cm^{-2}).

Figure 24. Kyropoulos method

Edge defined film-fed growth and the Stepanov method, which involve pulling crystals through shaped apertures, are shown schematically in Figures 25 and 26. The methods differ in their use of capillary action: in edge-fed growth, the die is wetted by the melt.

Edge defined film-fed growth (EFG) can be used to make single-crystal sapphire pipes but is employed on a large scale to make silicon ribbons for solar cells. Also thin-walled octagonal tubes are commercially produced by the EFG technique; they show reduced thermomechanical stress compared to edged ribbons. Octagons are then cut into wafers 10×10 cm, 300 µm thick with high-speed lasers. Crystalline quality is not usually important in such uses, and the plates, rods, and tubes made this way do contain some low-angle grain boundaries. Crystals grown by the Stepanov method are usually more crystallographically perfect but still tend to have large dislocation densities because of the large temperature gradients near the growth face.

Because the shaped crystals grown by these methods generally have at least one small dimension normal to the growth axis, high linear rates of growth (10 mm/min or more) can often

be maintained. With the Stepanov method, the crystal need not be pulled vertically upward, and equipment in which crystals are pulled vertically downward or horizontally has been described.

Figure 25. Edge defined film-fed growth

A special branch of high-speed crystalline fiber pulling through wetting and nonwetting dies with micro-orifices has been developed [142]. Small-diameter (50–300 μm) long single-crystalline fibers of numerous oxide materials (e.g., sapphire, $LiNbO_3$, $KNbO_3$) are of considerable interest for miniaturization, especially of multifunctional nonlinear optical devices.

Figure 26. Stepanov method

More details on shaped crystal growth are given in [143, 144].

Dendritic Crystallization. Around 1960, the use of dendritic crystallization was expected to provide the thin sheets of semiconductors needed to make transistors. However, the crystal quality was inadequate: dislocation densities and impurity concentrations were too high. Some workers believed that the material might be useful for solar cells. Certainly, the linear growth rates are attractive (rates of up to a few meters per minute have been reported). The method uses a multiply twinned seed crystal to grow tapelike crystals less than 1 mm thick. In diamond and zinc blende structure semiconductors, the preferred growth direction is <211>. In a typical process, a correctly oriented seed crystal is touched on the surface of a melt about 2 °C above its melting point. The melt temperature is then rapidly reduced by about 20 °C, and

pulling commences. An ingenious modification of the method uses two seeds to pull a so-called web crystal (Fig. 27).

Figure 27. Web growth

6.2. Bridgman Method

A crucible (Fig. 28) is lowered through a temperature gradient which straddles the melting point T_M. If a seed crystal is used and the convex growth face shown can be maintained, a single crystal with the same shape as the crucible should result. The seed crystal can be omitted, and a long, narrow tube can be substituted at the lower end, for example. (If several crystals nucleate, only one will probably emerge from a long, narrow tube.)

In practice, two particularly important problems exist. The first is that it is difficult to find crucibles with the same thermal expansion coefficient as the crystal. If the crucible has a larger coefficient, it will damage the crystal during cooling. If the crucible has a smaller coefficient, damage will occur if the crystal sticks to the crucible.

The other major problem is to obtain and maintain the desired temperature distribution (i.e., the interface shape shown). This requires crucibles with thermal conductivities that are less than those of the materials grown.

Figure 28. Bridgman crucible
Note the hatched seed crystal

Adding to these needs, the general requirement of no contamination makes crucible selection difficult. Common choices are graphite and silica which is often given a soft carbon coating. However, a variety of materials have been used, e.g., molybdenum for the growth of sapphire, iridium for $FeAl_2O_4$, boron nitride for gold, polyethylene for sodium nitrite, and polyester (e.g., Mylar) for ammonia.

Due to the rapid development of high-temperature construction materials in the 1990s and their application as growth containers (pBN, glassy carbon, etc.; see Section 5.3), the above-mentioned problems were solved for semiconductor compounds (GaAs, InP, GaP). Moreover, the sticking problem was suppressed by using a covering liquid layer (boron oxide) between the crucible wall and growing crystal. These technological improvements, together with the high diameter constancy and low defect density, led to a considerable renaissance of the Bridgman technique, which has become a serious competitor to the Czochralski method in the modern electronics industry [122, 135, 145, 146]. To prevent constitutional supercooling (Eq. 64), the growth rates (1–10 mm/h) are about one order of magnitude lower than in Czochralski growth because of the much lower axial temperature gradients used. Contemporary reviews on Bridgman growth of semiconductor compounds compared with Czochralski method are given in [122, 147 – 149].

Horizontal Boat Method. This method was established in the 1950s for GaAs growth and is still the most widely used production method for Si-doped material for optoelectronics. Pretreated (sand-blasted or etched) quartz and pBN boats are used. Usually, the charge is produced by in-situ synthesis in a separate ampoule, in which the volatile component (As) is evaporated and reacts with gallium held at a suitable temperature. Either the charge or furnace is moved (Fig. 29).

Figure 29. Horizontal boat configuration for the growth of semiconductor compounds

The major advantages are the possibility of stoichiometry control by means of the pressure of the volatile element from an additional source and the free growth of the shoulder region, which results in a low dislocation density of about 10^2 cm^{-2}. Main disadvantages are the noncircular cross section and the limited width of the shoulder. A review on semiconductor compound growth by this method is given in [150]. The succesful horizontal growth of single-crystalline sapphire and YAG plates by applying a restistance tungsten heater is described in [49].

Vertical Bridgman Method. The vertical bridgman method is characterized by the translation of the crucible containing the melt relative to the axial temperature gradient in a vertical furnace [151 – 153]. Whilst it is generally simpler in a mechanical sense to lower the crucible through the gradient, in some cases where vibration of the ampoule is a concern, the crucible is held stationary and the furnace is moved [135]. In the Bridgmann–Stockbarger mode [19], a high-temperature upper zone is followed by an adiabatic middle zone (for locating the position of the growing interface) and a low-temperature lower zone for afterheating and nearly gradient-free cooling. A wide range of materials (metals, semiconductors, oxides) are grown by vertical directional solidification. By connecting a third furnace in series, the stoichiometry of the growing crystal can be controlled by means of the partial vapor pressure of the volatile component, which has been succesfully applied to II-VI growth, for example [154].

Gradient Freeze. In this configuration both the ampoule and the furnace are held stationary, and the freezing isotherm is moved by computer-controlled modification of the furnace temperature (Figure 30). A multifurnace system consisting of 5 to 10 (a maximum of 50 has been described [135]) independently controlled heating zones is used to tailor the temperature field during growth (dynamic gradient freezing). Presently, high-quality semi-insulating GaAs crystals up to 10–15 cm in diameter with low dislocation densities in the range from 500 to 5000 cm^{-2} are grown commercially for high-frequency microelectronics [145, 146]. The reasons for such low dislocation density are the extremely low thermomechanical stress conditions (no sticking, no mechanical vibration, nearly uniaxial heat flow).

Figure 30. Vertical gradient freeze of semiconductor compounds (GaAs, InP) with stoichiometry control by means of a source of the volatile element (As, P) at T_s

Heat Exchanger Method. This container method, called HEM, is a modified directional solidification technique developed in the 1970s mainly for growth of large sapphire crystals from the melt [155]. But photovoltaic silicon, CdTe and BGO crystals have also been grown by this

method. Large crystals can be grown by HEM since it has a unique feature for independently controlling the heat input and heat extraction, as shown in Figure 31. A crucible with a single-crystal seed centered at the bottom is loaded with sapphire meltstock and placed on a high-temperature, helium-cooled heat exchanger. During melting the seed is cooled by helium gas flowing through the heat exchanger. Then, after melting and homogenization, the growth is initiated and progressed by increasing the helium flow and decreasing the furnace temperature. After complete solidification the furnace temperature and helium flow are reduced to achive in-situ annealing of the boule before the crystal is cooled in a controlled manner.

Figure 31. The principle of the heat-exchanger method

To remove trapped ambient gas from the liquid, the melt is overheated above the melting point without affecting the well-cooled seed. Morover, very low temperature gradients can be achieved. These features have allowed production of light-scatter-free sapphire crystals of 34 cm diameter and 65 kg weight. Growth of 50-cm diameter crystals is under investigation. Numerous cylindrical crystals can be prepared from such boules by core drilling.

6.3. Skull Melting Methods

Skull melting processes involve melting a powder charge (usually weighing over 50 kg) in a water-cooled container so that the melt is in contact only with an outer skull of sintered powder. When the system is cooled slowly, crystals nucleate at random and then progressively grow [156]. Figure 32 shows a version of the process using radio-frequency heating. Because the charge usually has an extremely high resistivity at room temperature, this version uses some lumps of the metal whose oxide is being grown to couple the radio-frequency energy to the charge. An alternative process [157] uses an arc to provide the power needed. The process is not very controllable and usually produces crystallographically imperfect crystals. However, for high-melting materials (MgO, CaO, SrO, BaO, and ZrO_2) the method has significant advantages and is used, for example, to grow about 1000 t of cubic zirconia per annum. For instance, Ceres Corporation (USA) produces approximately 20 t per month in 45 inch (117 cm) diameter skull furnaces holding 2.5–3.5 t of charge. The weight of the individual single crystals reaches 3–5 kg. At room temperature, pure ZrO_2 is monoclinic. The cubic form, which is stable at high temperature, can be made stable at lower temperature by doping (e.g., with CaO or La_2O_3). In addition, doping produces almost any color and this, combined with its hardness, large refractive index, and high dispersion, makes zirconia very attractive as a jewel. For further information on the growth, properties, and applications of this and other jewels, see [158].

6.4. Zone Melting

The methods described in Section 6.2 involve melting the entire charge and then progressively freezing it. However, the whole charge need not be molten. A crystal can also be grown by moving a molten zone through the charge [159]. This has the advantage that only part of the system must be at a high temperature at any time.

When the growth process is started with a charge having a uniform concentration c_0 of a solute with an effective distribution coefficient k, then the concentration in the crystal c_S at a distance x from the initial growth face is

$$c_S = k\, c_0 (1 - x/L_0)^{k-1} \tag{68}$$

where L_0 is the length of the charge and the process considered is one in which the whole charge is initially molten and then frozen. However, if a zone process is used with a zone length L, then for $x < L_0 - L$,

$$c_S = c_0 \left[1 - (1-k) \exp\left(-k\, x/L\right)\right] \tag{69}$$

Figure 32. Skull melting. The sequence of operations starts at the left

For $x > L_0 - L$, Equation (65 applies. Figure 33 gives an example of c_S as a function of x. The broken curve is the distribution obtained from Equation (65), i.e., the usual Bridgman case, which is referred to as normal freezing. The full curve labeled $n = 1$ is given by Equation (66) and is usually called a single-pass distribution. If the zone melting process is repeated (i.e., movement of another zone through the same bar), the distribution given by the curve for $n = 2$ is found. Further repetition gives curves for $n = 3$, 4, 5, etc., and an ultimate distribution is obtained which is shown by the line labeled $n = \infty$. These multipass distributions are the basis of zone refining [159], which is a useful method for purification provided the impurities have $k \lessapprox 0.2$. Designing a zone refining process for purification is not easy. A set of impurities with different k values must usually be considered. However, a process for which $n\,L/L_0$ is between 0.5 and 1.5 is a reasonable starting point.

In some processes, the charge is essentially pure, but doped crystals are to be produced by adding a dopant to the zone at the start of the process. If the concentration of dopant is c_0 in the zone, then the concentration in the solid is

$$c_S = k\,c_0 \exp\left(-kx/L\right) \tag{70}$$

If uniformly doped material is needed, the process is designed so that kx/L is small; in this way, crystals with very small gradients of dopant concentration can be obtained. When k is small, these gradients can be much less than those given by normal freezing, as shown when Equations (70) and (68) are compared.

The apparatus for zone melting a charge in a boat is fairly simple to design. All that is needed is a source of power which can heat a short length. Either the source or the boat can be moved.

In some cases, zone melting can be carried out without a boat [154]. A molten zone can exist between two solid rods, as shown in Figure 34. The power to maintain the molten zone can be supplied by electron bombardment, arc image systems, mirror-focused optical or thermal radiation, or laser beams. However, the use of radio-frequency heating as shown is the most popular method.

Figure 33. Concentrations (c_S) in the solid as a function of the initial charge concentration (c_0) and position x

Figure 34. Floating zone
For explanation of symbols, see text

If the zone starts in contact with a seed crystal and is then moved away from the seed, it can melt a polycrystalline nutrient and deposit a single crystal. The advantage of this method is that the molten material is only in contact with its own solid and a vapor phase (which, at least in principle, does not contain harmful impurities). The method has obviously desirable features for the growth of crystals of many reactive materials, but the only large-scale use is for silicon [160]. Oxygen-free silicon in bulk form can be grown only by the floating zone method.

If gravity and surface tension are the only forces affecting the zone size, then the parameter which determines stability is the zone length L (not the rod radius a), based on the assumption that the melt perfectly wets the solid and that the interfaces are flat. If γ is the surface tension (about 0.72 J/m^2 for silicon) and ρ is the density, the maximum zone length is

$$L_{\max} = K(\gamma/\rho g)^{1/2} \tag{71}$$

where K is a constant for which values of 2.5–3.5 have been given [160]. In practice, zone lengths lie between about 0.5 a and 2 a so that, as a first approximation, the maximum zone radius is

$$a_{\max} \approx 3(\gamma/\rho g)^{1/2} \tag{72}$$

For silicon $(\gamma/\rho\, g)^{1/2}$, the capillary constant, is 5.37 mm.

However, these two relations are based on rather doubtful assumptions, and a more realistic model should take account of the extra stabilizing forces resulting from electromagnetic effects when radio-frequency heating is used and the destabilizing force resulting from rotation. In a typical case, the electromagnetic forces exceed the surface tension forces. The pressure resulting from rotation is about

$$p = \rho \int_0^a \omega^2\, r dr$$

If this force should not exceed 10 % of the surface tension force (roughly γ/a), the rotation rate should not exceed

$$\omega_{\max} \approx (\gamma\rho/5\rho)^{1/2} a^{-3/2} \tag{73}$$

which for 10-cm diameter silicon gives a rotation rate of about 6 rpm. In general, Equation (70) appears to give values in the range used experimentally.

Global numerical models show that process optimization is sensitive to the shape of the field coil and the mass flow in the molten zone [161 – 163]. In addition to the flow caused by the relative rotations of the seed and nutrient rods, the large temperature gradients lead to density-gradient and surface tension-gradient (Marangoni) convection. There will also be electromagnetic forces causing flow when radio-frequency heating is used. If the aim is to produce uniformly doped silicon crystals, the best results appear to be obtained with short zones ($L \leq a$), rather low rotation rates (about half the value of $\omega_{\max}$), and growth rates in the range 2–4 mm/min. As with crystal pulling, dislocation-free growth can be obtained by growing a narrow neck from the seed. Under these conditions, about 800 t of silicon up to 15 cm in diameter is produced each year. Float zone material is usually purer (lower oxygen concentration) and tends to be used for high-voltage (power) devices, whereas Czochralski material is used for low-voltage devices, which have a much larger market.

The floating zone method has been used in research for a large number of materials, but apart from silicon, its commercial use appears to be limited to a few metals grown at rates of a few kilograms per year. The optical zone heating technique in mirror furnaces is of special importance in space experiments due to its low power consumption. It is also widely used in fundamental research for growth of dielectric substances [161]. Laser heating arrangements are used for production of oxide fiber crystals by miniature-zone floating [164]. For further data, see [48, 54, 142, 154, 160].

6.5. Verneuil Process

The traditional Verneuil apparatus (shown schematically in Fig. 35) uses an oxygen–hydrogen flame to melt a powder that is sprinkled into one or more of the gas streams. Other flammable gases (acetylene, synthesis gas, natural gas) can be used, and arcs, arc images, and plasmas have been used as the power source. The melt exists as a thin ($\lesssim$ 1 mm) film on the upper surface of the growing crystal. The powder must melt before or immediately after hitting the surface of this film. The process is controlled by the supply rates of heat and powder.

Figure 35. Verneuil process

The axial dopant and impurity distribution in Verneuil crystals follows the zone growth relation of Equation (66). This is due to the constancy of the liquid film volume continuously fed by molten source material.

An obvious refinement of the process is to surround the crystal by a furnace and so limit the temperature gradient in the crystal. This allows growth, for example, of ruby with dislocation densities below 500 cm^{-2}, but usually dislocation densities exceed 10^4 cm^{-2}. Typical growth rates range up to about 20 mm/h, but decrease roughly linearly as the crystal radius increases. Usual seed rotation rates are 5–50 rpm, with larger crystals requiring the slower rates. Diameters are, by modern standards, quite small: 20–50 mm is typical.

Up to the era of electronic clocks and watches, the largest use of the Verneuil process was to produce sapphire (undoped corundum) or preferably the harder ruby (chromium-doped corundum) for bearings in clocks and watches, at rates of up to 700 t/a. Because the hardness of the crystals increases, high dislocation densities could be an advantage for this type of application, although in practice, crystals with high dislocation densities tend to shatter when cut. Some ruby is still used for bearings, but the largest current use is for jewelry (a few hundred tons per year). Many refractory oxides and some other materials (e.g., niobium and silicon) have been grown for research purposes. Commercially available Verneuil-grown crystals include titania, strontium titanate, emerald, and a variety of spinels. The growth of 500 mm long laser crystals with a diameter of 40 mm has been reported [49].

7. Solution Growth Techniques

7.1. General Aspects

The properties of an ideal solvent are as follows:

1) Moderate reversible solubility of the material to be grown
2) Reasonable positive temperature coefficient of solubility
3) Production of crystals with useful habit
4) No formation of solid solutions with the solute
5) Low viscosity
6) Low volatility (except when evaporative methods are used)
7) Easy removal after growth
8) Compatibility with available containers
9) No reactivity with the gas phase
10) Ready availability
11) Inexpensiveness
12) Absence of toxicity

It is rare to find a solvent with all these properties. Many solvents are used for low-temperature

solution growth (Table 4 lists some examples), but the only commercially significant solvent is water. High-temperature solution growth is employed on a much smaller scale than low-temperature processes. Table 5 contains some examples. In commercial processes, lead salts are used widely for the growth of oxidic materials. The other popular solvent is gallium, which is used for the growth of GaAs and similar materials.

Table 4. Non-aqueous solvents for low-temperature solution growth

Solvent	Solutes
Acetone	acridine, trilaurin
Ethanol	hexamethylenetetramine
Carbon tetrachloride	benzophenone
Carbon disulfide	sulfur
Mercury	tin, iron

Table 5. Solvents for high-temperature solution growth

Solvent	Solutes
Lead difluoride, PbF_2	$ZnAl_2O_4$, ZnO
Lead oxide + lead difluoride, PbO + PbF_2	$Y_3Fe_5O_{12}$ and analogs, Al_2O_3, In_2O_3, $LiGaO_2$
Lead oxide, PbO	Al_2BeO_4, ferrites
Lead oxide + boric oxide, PbO + B_2O_3	$Y_3Al_5O_{12}$ and analogs
Bismuth oxide + boric oxide, Bi_2O_3 + B_2O_3	$GaFeO_3$, $Pb_3MgNb_2O_9$, garnets
Bismuth oxide, Bi_2O_3	$Bi_4Ti_3O_{12}$
Lead tungstate, $PbWO_4$	$Be_3Al_2Si_6O_{18}$
Potassium carbonate, K_2CO_3	$KTa_x\,Nb_{1-x}\,O_3$
Sodium tetraborate + boric oxide, $Na_2B_4O_7$ + B_2O_3	TeO_2
Potassium fluoride, KF	$KNbO_3$, $BaTiO_3$
Silicon, Si	SiC
Platinum, Pt	B
Gallium, Ga	GaAs, GaP, GaN, ZnTe
Tin, Sn	GaAs, ZnTe
Iron or iron + nickel, Fe or Fe + Ni	diamond
Tellurium, Te	CdTe

The supersaturation needed to produce crystal growth is usually achieved in one of three ways: cooling, solvent evaporation, or temperature gradient transfer. In this last method, solid nutrient material is placed in contact with the solution at one temperature, while the crystal grows in a region where the solution temperature is lower. The solute concentration c is assumed to be a function of temperature approximated by

$$c = c_0 \exp\left(-\Delta H_S / RT\right) \tag{74}$$

where c_0 is a constant and ΔH_S is the enthalpy of solution for simple materials.

The solvent is actively involved in the growth process. Changing the solvent can have marked effects on the crystals; e.g., the shape may change. In many cases, small amounts of other materials are added to solvents to produce the desired effects; for discussion, see [3] and [26].

7.2. Low-Temperature Methods

Figure 36 shows an apparatus suitable for low-temperature solution growth by solvent evaporation.

Figure 36. System for low-temperature solution growth by solvent evaporation

The basic components are an outer draught screen, an outer water bath with a propeller stirrer, and an immersion heater. A thermistor (+) below the immersion heater actuates the control system. In the inner solution bath, the crystals grow on seeds cemented to a "spider" which is rotated about the central axis alternately in clockwise and counterclockwise directions (one to four revolutions in each direction). The system has gaskets to seal all the joints; this is particularly necessary with deuterated solvents which are contaminated rapidly by atmospheric moisture.

By omitting the cooling pipe (shown hatched) and the gutter, the same apparatus could be used

for growth by slow cooling. The solution surface is often covered with an immiscible liquid to suppress evaporation; e.g., a layer of a silicone oil on the surface of an aqueous solution allows the use of high growth temperatures which are not practical when evaporation at the free surface is high. In slow cooling methods, the rates of cooling are usually less than 2 K/d. For a given system, the rate depends on the ratio of the area of the growth face to the volume of the solution and on dc/dT.

Figure 37 shows an apparatus for temperature gradient growth.

Figure 37. Growth by temperature gradient transfer

The system consists of two vessels in water baths, with appropriate stirring and temperature control. The crystal grows on a seed in the right-hand vessel at a temperature T_g, while in the left-hand vessel solution is saturated at a temperature $T_g + \Delta T$ by solid nutrient in a porous container. Because the centrally located pump can sweep undissolved solute from left to right along the upper pipe, some workers insert an extra tank at a temperature greater than $T_g + \Delta T$ at some point along the upper pipe. Cooling on the upper pipe and heating on the lower one may have to be provided if the temperatures in the two vessels are to be uniform.

In such systems the pump is the critical component: it can easily cause nucleation. Thus any pump should be placed in the flow from the crystallization tank. Pumps should be chosen to produce minimum pressure changes because nuclei tend to form in low-pressure regions.

Typical growth rates are small — usually less than 1 mm/d and occasionally below 0.01 mm/d. Hence, apparatus reliability is vital, and motors and bearings, for example, are usually much more robust than appears necessary for the loads borne. The possibility of power failures must be considered, and backup facilities capable of coping with the longest likely failure must be provided.

Numerous important oxide crystals, especially for applications in conventional and nonlinear optics, piezo- and pyroelectric devices, have long been grown commercially from aqueous solution. By controlling the pH of the solution very large perfect ammonium dihydrogenphosphate (ADP), potassium dihydrogenphosphate (KDP), potassium sodium tartrate (KNT), triglycine sulfate (TGS), and other crystals of dimensions 15 × 15 × 56 cm weighing up to 20 kg (ADP, KDP) can be produced by modified temperature transfer techniques (Fig. 37) in growth periods of up to 6 weeks [4].

Growth from aqueous solutions is becoming increasingly important for the production of crystalline biological macromolecules such as proteins. Commonly, microdialysis cells or liquid–liquid diffusion of a solvent or solute into a macromolecular solution are used. Crystallization results from gradual change in a property of the protein solution, such as pH. Crystals of small dimensions in the range of some hundred micrometers are obtained, suitable for structural X-ray and neutron diffraction analysis. However, the crystallization of biological macromolecules is a complicated multiparameter process, and extensive efforts are still required to understand the interactions of protein molecules in solution that govern nucleation and crystallization. More detailed information about this new important multidisciplinary branch of crystal growth are given in [165, 166].

7.3. High-Temperature Methods

High-temperature solution growth is sometimes called *flux growth* or *growth from a fluxed melt* because the solvents (Table 5) are often the fluxes used to dissolve oxide and other scum from metal surfaces. The principles involved are similar to those in low-temperature solution growth, but the technology differs because of the high temperatures and reactive liquids used. Solvent evaporation has been used in research, but only slow cooling and — to a minor extent — gradient transfer are used commercially.

For seeded growth, equipment is often arranged so that a seed attached to the crucible walls is not in contact with the solution until immediately prior to growth. This allows some superheating of the solution, which is necessary to ensure that no solid particles remain. When the solution is cooled to near its saturation temperature, the crucible is tilted or even rotated by as much as 180° about a horizontal axis to bring the seed into contact with the solution. At the end of growth, the tilting is reversed. To provide stirring, use is made of the accelerated crucible rotation technique (Section 4.2), in which the crucible is rotated alternately clockwise and counterclockwise about a vertical axis (Fig. 38). The construction involves welded joints at the top and bottom of the crucible. With care, the welds can be cut, the crystal removed, fresh nutrient added, a new seed fastened on, and the crucible resealed. Furnaces are made from ceramic tubes and bricks, with outer metal cases and refractory-wool thermal insulation. The heating elements are often silicon carbide rods which should not be operated at temperatures much higher than about 1300 °C.

Figure 38. Crucible system for seeded high-temperature solution growth
Gas cooling is used to ensure that the seed is at the coldest point

A spherical platinum crucible, optimal for forced convection arround the vertical axis and separation of the as-grown crystal from the flux by rotating around the horizontal axis, has been used to grow high-perfection yttrium iron garnet (YIG) crystals of about 100 g [90].

Figure 39 shows a gradient transfer system that can be conveniently placed in a heated ceramic tube. In such systems, the bottom of the crucible can easily be well insulated; radiative and convective heat loss from the top of the system then maintains the indicated temperature difference ΔT.

Figure 39. Crucible arrangement for seeded high-temperature solution growth by the gradient transfer method

For fluxes of low volatility, which allow the use of open crucibles, crystals can be grown at the surface of the melt when its temperature is lower than at the bottom. A seed crystal is introduced, as in Czochralski growth, but with a very small temperature gradient. The crucible temperature is continuously lowered at a cooling rate of 0.1–5 K/h. Such top-seeded solution growth (TSSG) is successfully applied to numerous perovskites and garnets.

High-temperature solution growth is widely used to produce thin crystalline plates of high-temperature superconductors like yttrium barium cuprous oxide $YBa_2Cu_3O_{7-x}$ [167]. Flux growth under high pressure is becoming important for the growth of GaN plates from Ga-rich solutions [168]. Specimens of good quality have been grown at 1400–1500 °C in 20 h under high N_2 pressure. They are attractive as homoepi-

taxial substrates for GaN thin-film deposition. However, an increase of the area from presently a few mm^2 to 100 mm^2 is required before any commercial fabrication of blue lasers on GaN substrates could be started.

Small diamond crystals are produced from graphite by dissolving in metallic fluxes (Ni, Co, Mn) at 5–6 GPa and about 1500 °C [4].

Figure 40. Traveling heater solution growth

Another form of temperature gradient growth is practiced by passing a solution zone along a rodlike bar. This can be done by making an assembly composed of a seed crystal, a disk of material with the initial solution composition, and a nutrient rod (probably of pressed powder) with the composition of the crystal to be grown. If this assembly is placed in a temperature gradient such that the seed is at the coldest point, the solution will migrate up the temperature gradient by dissolving nutrient at the hot face and depositing solid at the cold face. This process has the disadvantage that the growth temperature (i.e., the cold face temperature) rises as growth proceeds. The system shown in Figure 40, known as the travelling heater method (THM), overcomes this problem by having a stable zone length due to the use of a zone heater with a temperature maximum between the dissolving and solidifying interfaces. This method has been applied successfully to growing semiconductor mixed crystals such as (Ga,In)P and (Hg,Cd)Te with reduced dislocation density and homogeneous axial composition distribution [4, 169].

7.4. Liquid-Phase Epitaxy

Liquid-phase epitaxy (LPE) consists of a set of methods used for growing thin layers onto substrates. Epitaxy implies that the film and substrate have identical structure. However, in current usage the word means that the film is a single crystal with some crystallographic relation to the substrate. Often, but not always, the film and substrate have a common symmetry axis. Films on substrates can be strained elastically (Section 2.3). This strain can be so large that brittle materials crack and other materials suffer plastic deformation, giving rise to edge dislocations. These usually have a U shape, with the open end at the substrate surface and the closed end at a distance of about 2 h_c from that surface. It is possible to show that dislocations will not occur until the layer has a thickness h_c such that

$$h_c = \frac{3\,ba}{32\,\Delta a}\,[\ln(h_c/b) + 1] \tag{75}$$

for an abrupt change of the lattice constant by an amount Δa. Complete relief of the elastic strain then suggests a dislocation density

$$N_D = 4(\Delta a/ab)^2 \tag{76}$$

but this neglects the energy needed to create the dislocations, and in general N_D is much lower than predicted by Equation (73). The discrepancy is usually a factor of 10 to 100. A reasonable empirical estimate is

$$N_D \approx 0.1(\Delta a/ab)^2 \tag{77}$$

In practice, abrupt junctions are rare: some interdiffusion will occur and when the strain is $\sigma = \Delta a/a$, then the same geometrical arguments used to derive Equation (73) show that a dislocation density of $N_D = (1/b)\partial\sigma/\partial h$ is obtained, where h is the distance from the substrate surface. Again this value is an overestimate. However, for $\sigma \approx 0.1\,\%$, dislocation densities of 10^9 –10^{10} cm^{-2} have been observed in

regions within a few micrometers of the substrate surface. For further general discussion of epitaxy, see [170 – 172].

Figure 41. Liquid-phase epitaxy (LPE) by dipping
To produce growth, either the solution is supersaturated before the substrate is dipped, or it is marginally undersaturated before dipping and cooled while the substrate is immersed

Figure 42. Liquid-phase epitaxy (LPE) in a sliding boat
Growth is produced by either supersaturating the solution before it is moved onto the substrate or cooling while it is over the substrate

A wide variety of LPE methods have been used in research [57]. However, only two are employed on a large scale: the *dipping method* (see Fig. 41 for a representative example) and the *sliding boat process* (see example in Fig. 42). Dipping processes are used mostly for oxidic materials, and sliding boat processes for semiconductors.

Now as before, LPE is the most widley used thin-film deposition technique for large-scale production of light emitting diodes based on III-V semiconductors. The annual world production of LEDs amounts to 500×10^9.

Further information about LPE is given in references [54, 57], and [170 – 172]. Detailed reviews on fundamentals and technology of LPE are given in [173, 174].

7.5. Electrolytic Methods

Electroplating is a familiar process, and by using electrically conducting single-crystal substrates, single-crystal layers can be grown [175]. Bulk crystals can also be grown, but in general the process is rather slow. Thin layers of semiconductors have been grown from metallic solutions by this method; there is some dispute as to whether the principal effect is electroplating or whether growth results from the Peltier cooling which occurs at the semiconductor–metallic liquid interface. Both processes probably occur, and by suitable arrangement of the system, either can be made dominant. Layers can also be grown from nonmetallic solvents [176]. The limitation to conducting materials on conducting seeds, together with the fact that the process offers no particular advantages and some technological problems (e.g., the need to have both conducting and insulating materials in contact with the solution), has restricted the use of growth by electroplating, and there is no sign of its commercial use.

However, electroplating is only one of many electrolytic processes, and the use of electrolysis to change the valences of dissolved ions may be more important than direct electrolytic transport. The processes used include

1) Decomposition of the solvent to yield a supersaturated solution of the product, which is composed of atoms that were originally part of the solvent, e.g., MoO_2 crystals grown by

electrochemical decomposition of $K_2Mo_2O_7$ at 600 °C

2) Decomposition of the solvent to reduce the solubility of a solute, e.g., the growth of $Co_x V_{3-x} O_4$ from solution in $Na_2WO_4 + WO_3$

For further information about these processes which can yield a wide variety of oxides, borides, carbides, phosphides, sulfides, and arsenides, see [177]. None of the processes seems to have been exploited commercially.

7.6. Hydrothermal Growth

Temperature gradient transfer under hydrothermal conditions is used on a large scale for the growth of quartz. Hydrothermal conditions are taken to be temperatures and pressures near the critical values (i.e., 374.2 °C and 221.23 bar) (Fig. 6). Thus, hydrothermal growth could be regarded as intermediate between solution growth and vapor growth. In practice, the solvent is almost invariably a solution of a mineralizer in water; the mineralizer and the solute decrease the saturation vapor pressure and increase the critical temperature. In general, temperatures are less than 400 °C and pressures exceed 250 bar so that the solution is usually a liquid. The mineralizers are usually alkaline (NaOH or, less often, Na_2CO_3 for quartz), but neutral (e.g., alkali metal halides) or acidic (e.g., HI, HBr) mineralizers are also used.

Figure 43 is a schematic sectional view of an autoclave system which exaggerates the horizontal dimensions. Typical autoclaves for pressures over 1000 bar have ratios of height to internal diameter in the range of 16–20, and heights can be 8 m or more. For lower pressures, larger diameters (up to 1 m) and smaller heights (2.5 m) are used. The optimum ratio of external to internal diameter is 1.8–2.5. Thicker walls do not give appreciably higher working pressures.

The autoclave is loaded by putting the seed crystals in suitable racks, loading granular nutrient into the basket, and filling about 75 % of the free volume with the mineralizer solution. The concentration of this solution is usually about 1 mol/L. The autoclave is then sealed and heated to its working temperatures, e.g., 380 °C below the baffle and 350 °C above the baffle. The growth rate rises with the upper temperature, the temperature difference, the degree of fill (which governs the working temperature), the mineralizer concentration, and the amount of opening in the baffle (typically 2–10 %). For most applications of quartz, the growth temperature should be high, the mineralizer concentration should be less than 1 mol/L, and the other conditions are adjusted to limit the growth rate to less than 1 mm/d. Departing from these conditions gives crystals with too large a hydrogen content or too much other impurity to be useful in critical applications. According to the specifications to be met [178], the hydrogen content should not exceed about 200 atomic ppm (based on silicon); at higher hydrogen content, quartz is rather brittle. In current systems, up to 500 kg of quartz is grown in one run. Typical individual crystals weigh from a few hundred grams to several kilograms. For further data, see [48, Chap. 8], [55, Chap. 7.3] and [56, Chaps. 6 and 7]. A review is given in [179].

8. Vapor Growth Techniques

8.1. Sublimation and Evaporation Methods

Growth by evaporation and subsequent condensation is used widely to make thin epitaxial layers [134] and bulk crystals of a few materials

(mostly compounds of cadmium or zinc with sulfur, selenium, or tellurium.)

For an element (e.g., zinc), two methods are available. The material can be evaporated in a vacuum and condensed on some region which is on the line of sight from the source, or it can be evaporated into a gas stream which can be conveyed around corners provided it is not cooled until the deposition region is reached. With compounds, the choice of methods is larger. Some compounds evaporate congruently; these can be treated like the elements. However, most compounds do not evaporate congruently. For these, multiple sources (one for each component) can be used. Thus, vacuum evaporation or evaporation with one gas stream per component into gas streams that are combined in the deposition region can be employed. However, only one source can be used for vacuum evaporation if a small volume of the material is vaporized at one time. This process, called *flash evaporation,* can be achieved in several ways. For example, grains of the compound are dropped onto a plate heated to a very high temperature, or a bulk solid is exposed either to a laser beam [180], which is scanned over the solid surface and run in a pulsed mode (*laser-assisted evaporation*), or to an energetic gas plasma (*sputtering*) [181]. Other possibilities also exist: for example, one component can be evaporated into an inert gas stream which in the deposition region reacts with a gas:

$$\mathrm{Cd\,(g) + H_2S\,(g) \rightarrow CdS + H_2} \tag{78}$$

where the CdS is first formed as a supersaturated vapor which then deposits, usually as plates of the solid. For further information, see [58].

Bulk growth from the vapor has become important for two optoelectronic materials: ZnSe and SiC. Both compounds are of special interest for blue and blue-green light emitting diodes and lasers. Moreover, SiC is a suitable substrate for GaN epitaxy as well as for high-temperature high-power microelectronics. ZnSe monocrystals with diameters up to 6 cm and lengths of 3 cm are grown by seeded physical vapor transport [182]. SiC crystals are produced by the sublimation–condensation method in modified Lely reactors made of graphite, as shown in Figure 44 [183].

Figure 44. Schematic of a Lely reactor for the vapor growth of SiC single crystals (T_s = sublimation temperature, T_g = growth temperature)

Temperatures of $\geq 2200\ ^\circ$C are required for evaporation. The seed wafer is mounted to directly face the source of SiC powder. Usually, induction heating with frequency of 10 kHz or about 1 MHz and an argon atmosphere with a pressure of 130–5300 Pa are employed during growth at rates of 0.2–2 mm/h. Boules with diameters of 3–5 cm and a length of 2 cm are already produced commercially. Diameters 7.5 cm and 10 cm are under investigation. The main efforts are still directed towards the control of characteristic polytypes, lowering of dislocation density, and preventation of micropipes for growth in the <0001>direction. Such holes, with diameter of several micrometers, are caused by the strain field arround screw dislocations combined with the large value of the Burgers vector in this material. More information is given in [183].

8.2. Molecular Beam Epitaxy

Molecular beam epitaxy (MBE) is a refined evaporation process. Conventional evaporation sources have a rate of evaporation governed by the area of the evaporant and its temperature (or the partial pressure of the evaporant in the source region). Most MBE sources have large evaporant areas but are almost sealed. The rate of efflux from the source is governed by the area of the opening in the source and the partial pressure of the evaporant inside the source. Outside the source, the atmosphere is almost invariably an ultrahigh vacuum (usually less than 10^{-12} bar). Figure 45 shows the working region of a system and a typical source. To minimize the time

to reach the desired vacuum, the substrates and sources are often loaded and unloaded through a vacuum lock so that the main vacuum system is not routinely exposed to the atmosphere. The extreme vacuum used enables MBE films to be grown with very low substrate temperatures (< 100 °C), but in general, somewhat higher temperatures are needed (e.g., 200 °C) to obtain the desired properties. In the MBE growth of binary compounds, the flux of one component usually governs the growth rate, provided the other is available in excess; the excess of noncritical component is not consumed [184].

Figure 45. Simple system for molecular beam epitaxy (A) and typical source (B)
a) Outer vacuum jacket; b) Cryogenic screens; c) Source holders; d) Shutters; d) Cylindrical heater; f) Crucible; g) Thermocouples; h) Heater

Molecular beam epitaxy is a powerful method for making multiple-layer structures, such as multiple sandwich structures containing alternate layers of GaAs and AlAs, only two or three atomic layers thick. Such superlattices or quantum well materials have properties that differ radically from either bulk crystal [185]. Very sharp composition changes with dopants can also be obtained. However, MBE is usually a very slow process. Growth rates rarely exceed 1 μm/h so that the method is only viable for very thin layers. Molecular beam epitaxy is used in the production of semiconductor devices to a rapidly increasing extent. For further information, see [172] and [136, 184 – 186].

8.3. Chemical Vapor Transport

The bulk polycrystalline silicon, the nutrient material used in the Czochralski and floating zone processes, is prepared by decomposing volatile silicon compounds on hot silicon filaments by reactions of the type

$$2\,SiHCl_3 + 2\,H_2 \rightarrow 2\,Si + 6\,HCl$$

Such reactions can be used to deposit single crystal films onto single crystal substrates. This type of process is usually described as vapor-phase epitaxy (VPE). Because the reactants are produced outside the growth system, VPE is not strictly identical to chemical vapor deposition (CVD) in the sense described [187, 188], which involves in situ reactions such as

$$CdS\,(s) + I_2\,(g) \rightleftharpoons CdI_2\,(g) + 1/2\,S_2\,(g) \qquad (79)$$

However, all depositions involving chemical reactions are now described as CVD which is taken to include also mixed forms, for example,

$$AsCl_3 + Ga \rightarrow GaCl_3 + 1/2\,As_2 \qquad (80)$$

$$GaCl_3 + 1/2\,As_2 + 3/2\,H_2 \rightarrow GaAs + 3\,HCl \qquad (81)$$

(the reactions are schematic only). The $AsCl_3$ is provided from an external source.

Figures 46 – 48 give examples of these three types of growth. The first and last of these processes are widely used, and in some cases, there is an advantage in using a reduced pressure which increases the diffusion coefficients to give faster growth. For the growth of semiconducting compounds, use of the appropriate organometallic compounds can be a significant advantage [189].

Figure 46. Vapor-phase epitaxy of gallium arsenide

Figure 47. Vapor-phase epitaxy of silicon
a) Purifier; b) Reactor (1100–1200 °C)
Commercial reactors may contain up to 100 substrates; in these large reactors, the susceptor (often heated by radiofrequency) is tilted so that a greater gas flow rate (thinner boundary layer) compensates for the decrease of reactant concentration in the gas after it has passed over many substrates

Figure 48. Transport of cadmium sulfide by means of iodine

The use of these materials allows good control over growth so that complex structures composed of very thin layers can be grown. These structures have electronic properties not exhibited by bulk samples [190, 191]. Table 6 gives some examples of the layers that can be grown and the reactants used. For further information on VPE and CVD, see [55, 56, 58, 171, 172, 192 – 198]. Organometallic vapor-phase epitaxy is summarized in [199]

8.4. Vapor-Liquid-Solid Growth

In 1964 [37] the vapour-liquid-solid (VLS) mechanism was proposed for the first time to use such phase transition sequence for the growth of whisker crystals. A review is given by Givargizov, *Rost nitevidnykh i plastinchatykh kristallov iz para.*, Nauka, Moscow 1977. Today, such mechanism is of increasing importance for controllable production of nanowires and nanometer-sized structures–a rapidly expanding area with numerous applications, e.g., in electronics, photonics, biology, and medicine [200]. In the VLS growth mechanism, the reactants are supplied in the vapor phase by MBE, MOCVD, for example, and the diameters of the crystal whiskers are dictated by the size of metallic seed particles acting in molten form as localized solvent on a substrate. The material to be grown translates first from the vapor into the droplet due to the much higher absorption rate at the vapor–liquid surface compared with that at the surrounding solid substrate surface. The crystallization starts at the melt–solid interface between the droplet and substrate. The driving force for crystallization is the supersaturation within the droplet, which is continuously maintained by the material supply diffusing from the vapor–liquid interface to the liquid–solid one. As a result, a crystalline wire is growing under the continuously raising microdroplet (Fig. 49).

Figure 49. The VLS mechanisms demonstrating the growth of a silicon whisker crystal by using a gold microdroplet as solvent during a CVD or MOCVD process

Table 6. Organometallic chemical vapor deposition

Layer	Substrates	Reactants	Growth temperature, °C
AlAs	GaAs, Al_2O_3	$Al(CH_3)_3 + AsH_3$	700
AlN	Si, Al_2O_3, α-SiC	$Al(CH_3)_3 + NH_3$	1250
CdS	Al_2O_3	$Cd(CH_3)_2 + H_2S$	475
CdSe	Al_2O_3	$Cd(CH_3)_2 + H_2Se$	600
CdTe	Al_2O_3, BeO, GaAs	$Cd(CH_3)_2 + Te(CH_3)_2$	500
GaAs	GaAs, Ge, Al_2O_3	$Ga(CH_3)_3$ or $Ga(C_2H_5)_3 + AsH_3$	650–700
$GaAs_xP_{1-x}$	GaAs, $MgAl_2O_4$	$Ga(CH_3)_3 + PH_3 + AsH_3$	700–725
$Ga_xIn_{1-x}As_yP_{1-y}$	InP	$Ga(CH_3)_3 + In(CH_3)_3 + AsH_3 + PH_3$	670
GaN	Al_2O_3, α-SiC	$Ga(CH_3)_3 + NH_3$	950
GaP	GaAs, Si	$Ga(CH_3)_3 + PH_3$ or $P(C_2H_5)_3$	700 or 500
ZnS	Al_2O_3, BeO	$Zn(C_2H_5)_2 + H_2S$	750
ZnSe	Al_2O_3, $MgAl_2O_4$	$Zn(C_2H_5)_2 + H_2Te$	725
ZnTe	Al_2O_3	$Zn(C_2H_5)_2 + Te(CH_3)_2$	500

9. Solid-Phase Growth Techniques

9.1. Strain–Anneal Method

Before methods for handling materials without contamination were developed, growth from the solid state had very significant advantages. Contamination from surfaces in contact with other solids or with reactive atmospheres penetrated only a small distance because diffusion in the solid state is usually several orders of magnitude slower than in a liquid phase. Also, the apparatus was simple: almost any furnace would serve. At that time, the great interest was in metals or other ductile materials that could safely be strained. Later interest centered on rather brittle materials and, usually, on crystals with great crystallographic perfection. Thus, solid-phase growth techniques which tend to produce heavily dislocated crystals are of interest only when rather imperfect crystals of ductile materials are needed, such as materials with low loss and high permeability for very efficient transformers and motors.

In the strain-anneal method, the sample is first heated to a temperature high enough to ensure that it is not brittle (about half the absolute melting temperature for metals) and then subjected to a strain, usually between 1 and 10 %. The strain employed is critical. If σ_{opt} is the optimum strain, then strains less than $0.9\,\sigma_{\mathrm{opt}}$ or larger than $1.5\,\sigma_{\mathrm{opt}}$ will be less effective by a factor of two or more. The second stage of the process is annealing, which may be carried out to advantage with a temperature gradient across the sample. The annealing temperature is usually at an absolute temperature T which is an appreciable fraction (50–95 %) of the melting temperature on the same scale. If growth is going to occur, it is usually fast: 5–50 mm/h can be expected, but much higher rates (about 1 m/s) have been recorded [201]. The free energy to drive the process is the excess energy attributable to dislocations or small clusters of dislocations and grain boundaries. Ordered arrays of dislocations (small-angle grain boundaries) have lower energies per dislocation than isolated dislocations so that many samples grown by the strain-anneal method contain low-angle boundaries. For further data, see [4, 55, 202].

9.2. Methods Not Involving Applied Strain

In theory, the excess free energy of grain boundaries should be a driving force for crystallization. Although the energy per dislocation in a grain boundary is less than that for isolated dislocations, reducing the area of the boundaries (i.e., increasing the grain size) should decrease the sample free energy. This process occurs in many materials: metal workers exploit it on a large scale to control the properties of their materials. The extend to which it occurs is often related to purity. In particular, precipitated impurities stop grain boundary movements, and a common method for obtaining hard or creep-free metals is to add impurities that migrate to the grain boundaries. Thus, if impurities can be removed, grain growth can be expected. Solid-state electrolysis removes impurities and also heats the samples. To be effective, solid-state electrolysis should involve large current densities (several amperes

or even hundreds of amperes per square centimeter). Subsidiary heating can be applied to raise the sample temperature to a suitable value (55–90 % of the absolute melting temperature is usual). Growth rates can be 3–50 mm/h. For further information, see [203] and [204].

9.3. Solid-Phase Epitaxy

A solid in an amorphous (glassy) state has a higher free energy than the same solid in the form of a single crystal. The recrystallization of silicate glass over the centuries is a familiar process. This process is slow but can be accelerated by heating. It is now possible to create amorphous samples of many materials such as metallic alloy glasses by rapid quenching, and amorphous semiconductors by sputtering, for example, in hydrogen. For semiconductors, selective recrystallization of amorphous layers is now practiced on an increasing scale by the use of layer heating or other energy beam techniques [205 – 213]. Spatial control gives this process an obvious advantage. A less obvious but still significant advantage is that layers with much higher doping densities can be made by this method than by any other. Indeed, dopant concentrations can exceed the maximum equilibrium value.

9.4. Gel Growth

Gels can be regarded as soft pseudosolids. They are actually three-dimensional solid skeletons with liquid-filled interstices. The solid phase is often a network of silicon atoms surrounded by oxygen atoms in a tetrahedral geometry, which is made by hydrolysis of sodium silicate at about pH 8. Other gel-forming materials include gelatin, pectin, or potassium salts of fatty acids. Crystallization in a gel has the advantage of occurring in a strain-free environment, which is useful for some fragile solids that can deform under their own weight. Growth is usually produced by diffusing two solutions (one from each side of the gel) so that a supersaturated solution is created within the gel. With care or by providing a seed, one crystal can be grown. The diffusion rate in the gel is only slightly lower than in the pure fluid phase so the gel process is relatively rapid. The size L of a crystal generally increases with the square root of the time. This gives rapid growth when L is small but rather slow growth as L increases. Typically, L^2 increases at rates measurable in units of square millimeters per day or per week.

Examples of pairs of diffusants are:

1) Aqueous $(NH_4)_2CO_3$ and aqueous $CaCl_2$ to yield $CaCO_3$ crystals
2) CuCl in hydrochloric acid and pure water to yield CuCl crystals
3) Aqueous $AgNO_3$ and sulfuric acid to yield Ag_2SO_4 crystals
4) Pb $(CH_3COO)_2$ in acetic acid and aqueous KI to yield PbI_2 crystals

The technique does not appear to be used commercially. For further information, see [60].

10. Trends

Many methods are obviously available for crystal growth. The extent to which various methods are now used is discussed in Section 1.4, which shows that only few methods are employed to any significant degree. As the range of materials and uses increases, other methods will be employed more often; for example, the use of thin-film techniques is increasing. Table 7 gives production rates and their trends for the more extensively produced materials. Two other trends are also obvious. The first is that for economic reasons, larger crystals will be demanded. Costs of growth and subsequent processing decrease as crystal sizes increase. The second trend is the increasing demand for higher quality because greater purity and perfection, as well as tighter control over dopant distribution, are needed to raise yields and device performance. Decreases in device dimensions and increases in yields may change the quantities of particular materials needed, and some substitution of noncrystalline materials can be expected, e.g., amorphous semiconductors. However, an increasing demand for crystals and for crystals grown to tighter specifications can confidently be expected. To meet these demands at reasonable cost will require better apparatus with more extensive use of automation and better understanding of the mechanisms of crystal growth. Thus, although fewer people may be involved with crystal production, more effort is likely

to be required in process development and research.

Table 7. Annual production rates and trends

Crystal [a]	Production [b] >, t/a	Trends [c]
Silicon	10 000	up
Metals	4000	up [d]
Quartz	2500	constant
III-V compounds [e]	800	constant
Ruby	500	down
Alkali halides	400	down
Germanium	400	constant
Garnets	100	up
Lithium niobate	100	up
Phosphates [f]	20	down
Lithium tantalate	15	constant
Cubic zirconia	2000	up
TGS [g]	10	constant
Diamond	10	up
II-VI compounds [h]	5	up

[a] Crystals of more than 100 other materials can be bought.
[b] Averages; data for Russia, China, etc., are rare so that errors could range from −20 % to + 30 %.
[c] Trends are averaged; some materials show rapid fluctuations, e.g., quartz.
[d] The upward trend for metal crystals is very rapid.
[e] GaAs, GaP, InP, InSb, etc.
[f] Ammonium and potassium dihydrogen phosphates and their analogs.
[g] Triglycine sulfate and similar materials used mainly for pyroelectric devices.
[h] CdS, CdTe, etc.

Calcium cyanamide is produced from calcium carbide and nitrogen gas by an exothermic solid nitrogenation at 1000°C. It is used as a slow release nitrogen fertilizer with beneficial side effects against soilborne deseases. In chemical industry, it is the base for cyanamide and thiourea chemistry.Cyanamide is a fairly stable, toxic substance obtained from calcium cyanamide by reaction with water and carbon dioxide. It has vast applications in industrial nitrogen organic chemistry, and is also directly used as a plant protection agent.Dicyandiamide is derived from cyanamide by dimerization in presence of alkali. The nontoxic compound has found widespread industrial applications in resins, plastics, water treatment, and pharmaceuticals.

1. Calcium Cyanamide

Calcium cyanamide was probably first obtained in the laboratory in 1877 by heating calcium carbamate to red heat [3]. In 1889 it was prepared in larger quantities by heating thoroughly mixed, finely pulverized urea and calcium oxide [4]. A commercial process for the nitrogenation of calcium carbide, the Frank – Caro process, was patented in Germany in 1895 [5]. A calcium cyanamide plant using a batch oven furnace was erected at Piano d'Orta, Italy, in 1905. At about the same time, the Polzeniusz – Krauss channel furnace was put into service. By 1910, plants were established in Germany (Bayerische Kalkstickstoffwerke; AG für Stickstoffdünger), France, Japan, Sweden, Switzerland, and the United States (American Cyanamid).

Calcium cyanamide [*156-62-7*], CaNC≡N, M_r 80.10, is the neutral salt of cyanamide, NH_2CN (see Chap. 2); it is also known as lime nitrogen, nitrolime, and kalkstickstoff.

Industrial-grade calcium cyanamide contains, in addition to $CaCN_2$, ca. 20 % CaO and 10 – 12 % free carbon, which gives the product its gray-black color. It also contains a small amount of nitrides formed from silica and alumina. The total nitrogen content varies from 22 to 25 %, depending on the raw materials used. Of the total nitrogen, 92 – 95 % is present as cyanamide and 0.1 – 0.4 % as dicyandiamide; the remainder is present as nitrides.

1.1. Physical Properties [6]

Pure calcium cyanamide is a colorless hygroscopic salt, which forms rhombohedral crystals. In a nitrogen atmosphere, it melts with decomposition at 1300 °C. Other physical properties are given below.

Density at 25 °C	2.36 g/cm^3
Heat of fusion	54 kJ/kg
Specific heat, 20 – 100 °C	909 J/kg
Enthalpy of formation ΔH_{298}	− 348 kJ/mol
Free energy of formation ΔF_{298}	− 303 kJ/mol
Normal entropy S	87.1 J mol^{-1} K^{-1}

1.2. Chemical Properties [6]

Calcium cyanamide decomposes above 1000 °C in a way that depends on the temperature, the partial pressure of nitrogen, and impurities present. The principal decomposition products formed by heating under vacuum or in an inert gas are calcium carbide, calcium metal, and nitrogen:

$$2\,CaCN_2 \rightarrow CaC_2 + Ca + 2\,N_2$$

Decomposition at higher nitrogen pressure gives primarily cyanide products. Calcium nitride and carbon are always formed.

Calcium cyanamide reacts with oxygen and carbon dioxide, starting at ca. 475 °C, with formation of nitrogen and calcium carbonate; calcium oxide forms above 850 – 900 °C. Carbon present as an impurity cannot be removed by oxidation, which attacks calcium cyanamide preferentially.

Carbon monoxide and calcium cyanamide react above 1000 °C to form CaO and calcium carbide.

The reactions of calcium cyanamide in aqueous solution are determined primarily by temperature and pH [7]. At room temperature, monocalcium cyanamide $Ca(HCN_2)_2$ forms; when heated at pH 9 – 10, this is converted to calcium hydroxide and dicyandiamide $(NH_2)_2CNCN$ (see Chap. 3). Below 40 °C, cyanamide is obtained at pH 6 – 8; lime is precipitated with carbon dioxide.

Urea is formed in the presence of acid and catalysts, and thiourea in the presence of sulfides.

At 200 °C under pressure, calcium cyanamide is hydrolyzed to ammonia and calcium carbonate in an alkaline medium. The reaction was employed to produce ammonia in the early1900s.

1.3. Production

1.3.1. Overall Process

Calcium cyanamide is manufactured in three steps. First, lime is made by heating high-grade limestone:

$$CaCO_3 \rightarrow CaO + CO_2$$

Second, calcium carbide is synthesized from lime and coke or coal in an electric furnace:

$$3\,C + CaO \rightarrow CaC_2 + CO$$

Electric resistance heating is used to melt the lime and effect the endothermic reaction with the coke (→ Calcium Carbide).

Third, calcium cyanamide is synthesized from calcium carbide and nitrogen. This reaction is exothermic but requires heating of a portion of the reaction mixture to the initiation temperature of 900 – 1000 °C:

$$CaC_2 + N_2 \rightarrow CaCN_2 + C$$

The heat source is then removed [7]. The reaction continues by controlled addition of nitrogen; it produces 286.6 kJ/mol at 1100 °C, and 295 kJ/mol at 0 °C.

Mechanism. It is believed that calcium cyanamide is formed through a number of intermediates, such as $Ca(CN)_2$, CaC_2N_2, CaC, and Ca_2N_2 [8 – 10]. However, in the nitrogenation of calcium carbide, the main products are calcium cyanamide and carbon. Above 1000 °C, cyanide also forms and is in equilibrium with cyanamide and carbon:

$$CaCN_2 + C \rightleftharpoons Ca(CN)_2 \quad \Delta H_{298} = 163\,\mathrm{kJ/mol}$$

This reaction is endothermic, whereas the nitrogenation is exothermic.

Above 1160 °C, the system $CaCN_2$ – C – $Ca(CN)_2$ melts, with over 60 % cyanamide present at equilibrium.

Small amounts of cyanide present at the usual reaction temperatures of 1000 – 1100 °C are

rapidly converted to calcium cyanamide by slow cooling; the cooled product is practically free of cyanide.

The cyanamide – cyanide equilibrium is shifted towards cyanide by addition of alkali metal halides. The yield of cyanide can be improved by quick cooling. This was the basis of the fusion cyanide process to produce crude sodium cyanide for metal leaching. A recent investigation showed, that a calcium cyanamide conversion efficiency of up to 95 % can be reached. Most cyanide used for ore leaching however is made from hydrocyanic acid. [182]

Nitrogenation Byproducts. Technical-grade calcium carbide contains impurities that, during nitrogenation, lower the yield of desired product. This is because silica and alumina, which are only partially reduced in the carbide furnace, are present in the carbide raw materials. In the nitrogenation, Al_2O_3 and SiO_2 react with $CaCN_2$ to form nitrides.

$$3\,CaCN_2 + Al_2O_3 \rightarrow 3\,CaO + 2\,AlN + 3\,C + 2\,N_2$$

$$3\,CaCN_2 + SiO_2 \rightarrow 2\,CaO + CaSiN_2 + 3\,C + 2\,N_2$$

Industrial-grade calcium carbide also contains calcium hydroxide and calcium carbonate. On heating, water and carbon dioxide are liberated; reaction with carbide gives acetylene. As a result, hydrogen, formed by decomposition of acetylene, is always found in the exhaust gas of the nitrogenation furnaces.

These side reactions and the inadvertent introduction of some oxygen during the nitrogenation reduce the overall yield by ca. 10 %. The purest possible raw materials give the most favorable results economically.

Catalysts. Various catalysts that act as fluxes are used to accelerate the reaction or lower the required temperature. The most commonly used are calcium chloride and calcium fluoride. Their function is not completely clear, but they may provide a liquid phase in which the reaction can occur. The product is in the form of a well-sintered pig, indicating the presence of a liquid phase at some stage of the reaction.

Rate studies have shown that calcium fluoride reduces the temperature of optimum reactivity and increases the reaction rate by a factor of 4.5 at 1000 °C [11].

Reaction Kinetics. The conversion rate depends on temperature, nitrogen partial pressure, carbide purity, and the presence of additives. The crystallite size also plays a part. High-grade carbide consisting of coarse crystals reacts more slowly than lower-grade carbide of lamellar structure. As indicated above, metal halides accelerate the reaction.

In the nitrogenation of calcium carbide, the reaction proceeds inward from the grain surface. The rate of nitrogen transport through the porous layer is a determining factor at lower temperature, whereas the chemical reaction at the boundary layer is decisive at higher temperature and in the presence of additives. The dependence of the rate constant on temperature, additives, and nitrogen pressure has been reported [12]. Figure 1 shows the effect of nitrogen pressure.

Figure 1. Rate of calcium carbide nitrogenation as a function of nitrogen pressure [12]
Powdered CaC_2 (67 %) containing 1.2 % CaF_2 used.

1.3.2. Manufacture

Both batch and continuous processes have been used to prepare calcium cyanamide [13]. The more important processes are the Frank – Caro batch furnace process and the Trostberg rotary furnace process. In these processes, the exothermal reaction between carbide and nitrogen takes place between 1000 and 1150 °C. In the continuous rotary furnace process, the reactants, except at the beginning, are heated exclusively by the heat of reaction, whereas the batch furnace process requires ignition for each batch.

Frank – Caro Batch Oven Process [11]. The batch oven process was widely used in the first half of the 20th century. Today, it has much less importance due to unfavorable nitrogenation yields, higher labor costs and lower throughput. It employs a batch reactor filled with up to 10 t of ground calcium carbide. After initial ignition by electric heating or a pyrotechnic mixture, the reaction proceeds spontaneously. Nitrogen gas is introduced through inlets in the furnace shell. The total reaction lasts several days and leads to a sintered block of calcium cyanamide, which is broken into pieces and milled.

Trostberg Rotary Furnace Process. In this continuous nitrogenation process, ground lime nitrogen (crude calcium cyanamide) is metered onto a material bed in a broadened part of the rotary furnace in such a way as to keep the carbide concentration in the bed as low as possible. The process is controlled by varying the carbide content.

The rotary furnace developed by SKW Trostberg (now Degussa AG) is ca. 20 m long and includes the broadened furnace head, where the main reaction takes place [14]. The furnace is lined with fireclay.

Ground carbide with a CaC_2 content of 55 – 60 % is continuously mixed with calcium fluoride and ground lime nitrogen and is blown into the furnace with nitrogen. The average residence time of the solid is between 5 and 6 h. The reaction product is a granular or powdered lime nitrogen, which is transferred from the rotary furnace to a cooling drum. The heat released by the reaction is sufficient to bring the starting materials to the desired temperature of 1000 – 1100 °C. After the furnace has been started, it remains in operation without external heating for many months. The capacity of a unit is about 25 t/d of fixed nitrogen (Fig. 2).

Other Processes. Because large amounts of energy are consumed, particularly in the preparation of calcium carbide, less energy intensive methods for manufacturing calcium cyanamide have been examined. Between 600 and ca. 1000 °C many reactions of lime with nitrogen compounds containing hydrogen or carbon lead to calcium cyanamide. Compounds such as hydrocyanic acid, dicyanogen, urea, and dicyandiamide form calcium cyanamide with lime.

Figure 2. Trostberg rotary furnace process
1) Calcium carbide lump silo; 2) Crusher; 3) Crushed carbide silo; 4) Calcium fluoride silo; 5) Calcium cyanamide silo; 6)- 8) Weigh feeders; 9) Tube mill; 10) Homogenizing; 11) Milled carbide silo; 12) Calcium cyanamide silo; 13), 14) Weigh feeders; 15) Rotary furnace; 16), 18) Dust filters; 17) Rotary cooling tube; 19) Crusher; 20) Silo; 21) Weigh feeder; 22) Tube mill

Lime and urea form calcium cyanate [15], which on heating is converted to calcium cyanurate and finally to calcium cyanamide:

$$CaO + 2\,H_2NCONH_2 \xrightarrow{200\,°C} Ca(OCN)_2 + H_2O + 2\,NH_3$$

$$3\,Ca(OCN)_2 \xrightarrow{400\,°C} 2$$

$$\xrightarrow{700\,°C} 3\,CaCN_2 + 3\,CO_2$$

Lime reacts with hydrogen cyanide [16] at 750 – 850 °C:

$$CaO + 2\,HCN \rightarrow CaCN_2 + CO + H_2$$

The reaction of lime with ammonia and carbon monoxide at 700 – 900 °C produces 99 % calcium cyanamide:

$$CaO + 2\,NH_3 + 3\,CO \rightarrow CaCN_2 + 2\,CO_2 + 3\,H_2$$

The above processes give white calcium cyanamide, whereas the product obtained from limestone and coal always contains carbonaceous impurities. None of these processes have yet been commercialized because of cost or poor yield [13].

1.3.3. Processing of Technical Calcium Cyanamide

Crude calcium cyanamide is reduced in size and ground in tube mills to allow passage through a 0.2-mm screen. If calcium cyanamide is sold in granular form, grinding is omitted and the desired grain size is separated by screening.

When the carbide content is above 0.1 %, as in the Frank – Caro process, calcium cyanamide is degassed by treatment with water to convert the carbide to acetylene and calcium hydroxide. For environmental and safety reasons, the acetylene-containing off-gas must be incinerated and scrubbed to remove acidic byproducts.

Granulation. Because of the dust problems associated with finely ground calcium cyanamide in fertilizer applications, the product is oiled. Alternatively, it is converted to a more compact form by granulation or compression. Granulation with calcium nitrate solutions gives a fine, finished calcium cyanamide bead. This form affords a nitrate nitrogen system that can be used directly in the plant as starter nitrogen. In addition, it affords a slowly acting cyanamide nitrogen source. This product has an almost unlimited storage life, because the free calcium oxide is completely hydrated and no expansion can occur. In Europe, Degussa AG is the main producer of beaded calcium cyanamide.

1.4. Quality Specifications

Commercial-grade calcium cyanamide has approximately the following composition:

Total nitrogen	19 – 20 %
Cyanamide nitrogen	ca. 15 %
Nitrate nitrogen	ca. 2 %
Dicyandiamide nitrogen	0.4 – 0.7 %
Other nitrogen	2.0 – 2.5 %
Total calcium oxide	53 – 55 %
Water (chemically bound)	7 – 8 %

Total nitrogen is determined by the Kjeldahl or Dumas method.

1.5. Storage and Transportation

Calcium cyanamide is stored in warehouses or silos, but storage life with free calcium oxide is limited because the latter is expanded by moisture.

Bags used for ground and granular calcium cyanamide must be moisture-tight to prevent grain breakdown and expansion. Polyethylene valve bags in combination with multilayer paper bags are excellent for granular calcium cyanamide. Paper and plastic bags are used for the less sensitive beaded product.

Calcium cyanamide with a calcium carbide content below 0.1 % is not classified as dangerous goods according to transport regulations. If the calcium carbide content exceeds 0.1 %, calcium cyanamide has to be classified as UN class 4.3 (substances that emit flammable gases upon contact with water), UN no. 1403, packaging group III, hazard label 4.3 according to actual UN regulations on transport of dangerous goods.

1.6. Uses

Calcium cyanamide is used in agriculture and horticulture predominantly in Europe and Asia as a slow-release nitrogen fertilizer which exhibits beneficial side effects against soilborne plant diseases, slugs, and germinating weeds. The fertilizer is broken down by soil moisture into highly reactive lime and free cyanamide. The latter is responsible for the fertilizer's fungicidal and herbicidal side effects. Within a few days, soil microbes convert the cyanamide to urea and then to ammonia. A second known pathway leads to dicyandiamide, which acts as a nitrification inhibitor in the soil. In this way, the conversion of ammonia nitrogen into nitrate is slowed down for several weeks, and leaching of fertilizer nitrogen is prevented (see also → Fertilizers). Calcium cyanamide is particularly valuable for intensively used soils that are highly infested with soilborne pathogens which cause root and stem rot [17, 18].

Recent developments in urea fertilizers use a calcium cyanamide core within urea granules to stabilize nitrogen against nitrification [19, 20].

Calcium cyanamide is also used to control animal pests on pasture. When applied to grassland, it kills the dwarf water snail, which is the intermediate host of the liver fluke. It also kills eggs and larvae of gastric and intestinal parasites in the grass and controls salmonella in liquid sewage.

Over 99 % of nitrogen oxides are effectively removed from waste gases by scrubbing with calcium cyanamide [21]. In Portland cement, cyanamide and calcium cyanamide improve setting characteristics, increase compressive strength, and reduce freeze – thaw damage [22].

Pharmaceutical-grade calcium cyanamide is used to treat alcoholism. A small pill taken once a day subjects the alcohol abuser to an unpleasant flush (see Chap. 5), which discourages drinking [23]. Calcium cyanamide is used for steel nitridation [24] and, to some extent, for desulfurization [25]. It has various uses in the chemical industry for the production of cyanamide, dicyandiamide, and thiourea.

1.7. Legal Aspects

Calcium cyanamide is listed in global inventories of existing chemicals, e.g., EINECS (European Union), TSCA Inventory (United States), DSL (Canada), AICS (Australia), IECSC (China) and MITI (Japan). Within the European Union, cyanamide is classified as harmful (danger symbol X_n), R41(risk of serious damage to eyes), S22 (do not breathe dust) and S36/37/39 (wear suitable protective clothing, gloves and eye/face protection). In Germany, calcium cyanamide is classified in water hazard class 2 (hazardous for waters).

2. Cyanamide

Cyanamide [*420-04-2*], $NH_2C{\equiv}N$, M_r 42.04, was first obtained in 1838 by passing gaseous ammonia over cyanogen chloride [26]. Another pathway was the desulfurization of thiourea by means of lead or mercury compounds [27]. Just after the discovery of the calcium cyanamide process, the laboratory synthesis of cyanamide became more convenient [28, 29]. However, the latent instability of cyanamide prevented its industrial-scale production and usage until processes were developed around 1965 to purify and stabilize cyanamide in aqueous solution and in crystalline form.

Recently, cyanamide has been found in nature. Hairy vetch (*Vicia villosa*) produces free cyanamide from inorganic nitrate, obviously as an allelochemical to compete against neighboring plants [30, 31]. Cyanamide is regarded as a key intermediate within chemical evolution on earth billions of years ago [32]. It is therefore not astonishing that cyanamide metabolism is common in nature.

2.1. Physical Properties [6]

Cyanamide forms colorless, deliquescent orthorhombic crystals or long transparent needles (from water) [33], large platelike crystals when allowed to crystallize spontaneously from water, and crystals from dimethyl phthalate solution [34]. The crystal structure of solid cyanamide has been thoroughly investigated [35]. Physical properties are listed below.

Melting point	46 °C
Vapor pressure at 20 °C	5×10^{-3} mbar
Crystal density	1.282 g/cm^3
Melt density at 57 °C	1.069 g/cm^3
Refractive index n_D^{48}	1.4418
Enthalpy of formation at 25 °C	+ 61.3 kJ/mol
Specific heat (0 – 39 °C)	2.291 J/g·K
Latent heat of fusion	8.76 kJ/mol
Latent heat of vaporization	70.5 kJ/mol
Heat of solution (in water)	+ 15.1 kJ/mol
Enthalpy of dimerization to dicyandiamide at 25 °C	− 48.8 kJ/mol
Enthalpy of hydration to turea at 25 °C	− 109 kJ/mol
Dissociation constant pK_a	10.3

Figure 3. Solubility of cyanamide in water

Cyanamide is a weak acid that is very highly soluble in water. It is completely soluble at 43 °C, and has a minimum solubility at − 15 °C (Fig. 3). It is highly soluble in polar organic solvents, such as alcohols, ethers, esters, nitriles

and amides, but less soluble in nonpolar solvents like saturated, halogenated, or aromatic hydrocarbons. Ketones are not recommended as solvents for cyanamide, because they tend to react under certain circumstances.

The IR spectrum of cyanamide exhibits an intense, poorly resolved doublet at 2225 – 2260 cm^{-1}. The UV spectrum shows only weak absorption below 230 nm, with no maximum observable above 208 nm. The infrared and Raman spectra support the *N*-cyanoamine structure, $NH_2-C\equiv N$ [22].

2.2. Chemical Properties

Cyanamide can be regarded as the amide of cyanic acid or as the nitrile of carbamic acid. The difunctional molecule is capable of reacting as a nucleophile at the amino group or as an electrophile at the cyano group. Many reactions with polyfunctional compounds involve both reactive sites, thus forming heterocyclic structures.

Cyanamide exists in two tautomeric forms that cannot be isolated in pure form:

$$\underset{\text{Nitrile form}}{H_2N-C\equiv N} \rightleftarrows \underset{\text{Carbodiimide form}}{HN=C=NH}$$

Spectroscopic evidence and reactivity clearly show that the cyanamide form predominates by far. However, in some special reactions, e.g., silylation and stannylation, cyanamide reacts solely as the carbodiimide form.

Oligomerization. One of the most important reactions of cyanamide is *dimerization* to cyanoguanidine (dicyandiamide). Unless kept cool and stabilized by weak acids, crystalline cyanamide may polymerize violently. In aqueous solutions, polymerization becomes significant above pH 5, with a maximum reactivity between pH 8 and 10

Melamine [*108-78-1*] was produced until around 1975 from dicyandiamide at elevated temperatures and pressure. Liquid ammonia, with or without an organic solvent, is a suitable reaction medium [36]. The mechanism of *trimerization* has not been established, but it is believed to involve either the reaction of a molecule of cyanamide with a molecule of dicyandiamide or the reaction of two molecules of dicyandiamide to form guanylmelamine, which breaks down into melamine and cyanamide (→ Melamine and Guanamines).

Reaction with Water. The hydrolysis of cyanamide to urea is catalyzed by acids. In aqueous solution cyanamide has the highest stability between pH 4.0 and 4.5. At lower pH, especially in the presence of strong mineral acids, the hydration reaction may become violent and can lead to vapor explosions if the heat is not dissipated [37].

Reaction with Hydrogen Sulfide or Hydrogen Selenide. Thiourea [*62-56-6*] can be prepared by the action of hydrogen sulfide on an aqueous solution of cyanamide with ammonia as catalyst. The optimum conditions are pH 8 – 9 and a temperature above 50 °C [38].

$$H_2NCN + H_2S \rightarrow H_2NCSNH_2$$

Selenourea [*630-10-4*] is obtained similarly from hydrogen selenide [39].

$$H_2NCN + H_2Se \rightarrow H_2NCSeNH_2$$

Reaction with Thiols and Thiophenols. Cyanamide reacts with thiols and thiophenols more readily than with alcohols and phenols; the products are pseudothioureas. The reaction is conveniently conducted in diethyl ether.

Reaction with Alcohols and Phenols. Under suitable conditions, cyanamide reacts with alcohols and phenols to give *O*-alkyl- and *O*-arylisoureas (also called pseudoureas). Alkylisoureas are usually prepared as hydrochlorides by treating a solution of cyanamide in the appropriate anhydrous alcohol with dry hydrogen chloride; sulfuric acid has also been recommended [40].

The alkylisourea bases, which have basic strengths K_b of around 1×10^{-4} [41], can be liberated from their salts by treatment with moist potassium hydroxide under ether or with sodium alkoxides in anhydrous alcohols. They are fairly stable under normal conditions but are sensitive to moisture and dissociate when heated.

O-Alkylisourea compounds exhibit a significant alkylating power. The hydrohalide or carboxylate salts decompose to urea and alkyl halides or alkyl carboxylates upon heating to temperatures above 100°C. Because of their potential mutagenic properties, these compounds should be handled with care.

The synthetic potential of *O*-alkylisourea compounds is based on its ease of reaction with simple amines to form guanidines, thus acting as an activated form of cyanamide in a guanylation (or amidination) reaction. In addition, *O*-alkylisoureas are the ideal reagents to build up 2-alkoxypyrimidines or 2-alkoxy-1,3–5-triazines.

O-Methylisourea can be nitrated to *O*-methyl-*N*-nitroisourea, useful as a nitroguanylation agent [42].

Reaction with Ammonia and Amines. Ammonia adds readily to the nitrile group of cyanamide to form guanidine. Weakly acidic conditions help to avoid dimerization and, in aqueous systems, hydrolysis to urea.

where X = halogen.

Primary and secondary amines react with cyanamide to form substituted guanidines under the above conditions.

Reaction with Amino Acids. Cyanamide adds to amino acids to form carboxyalkylguanidines. The conversion of glycine to glycocyamine was the first such reaction reported [43].

Sarcosine reacts with cyanamide to form creatine [44, 45], which can be further processed to creatinine at higher temperatures [46].

Cyanamide and dialkylcyanamides can be used as coupling agents to induce the formation of peptide bonds when heated with *N*-benzyloxycarbonyl amino acids and amino acid esters [47]. This dehydrating effect is ascribed to the intermediate formation of an *O*-acylpseudourea or amino anhydride, which reacts further with the amino ester [48].

Reaction with Hydrazines and Hydrazones. Cyanamide reacts with hydrazines to form aminoguanidines, which are versatile intermediates for the synthesis of nitrogen-rich compounds, particularly heterocycles. Aminoguanidine [*79-17-4*], itself unstable, is conveniently isolated as the relatively insoluble hydrogen carbonate after reaction of aqueous hydrazine with cyanamide at around pH 6 [49, 50].

Aminoguanidine salts react further with hydrazine in aqueous or alcoholic solution to give salts of 1,2,3-triaminoguanidine [*2203-24-9*] [51].

The reaction of cyanamide with phenylhydrazine hydrochloride in boiling alcohol produces two isomeric aminoguanidines [52].

Reaction with Hydroxylamines. Hydroxylamine hydrochloride reacts slowly with aqueous cyanamide to give hydroxyguanidine [*13115-21-4*] [53].

Cyanide, also that present in crude calcium cyanamide (see "Black Cyanide" in Chapter 1.3.1) can react with cyanamide via unisolable intermediates forming oxalate upon hydrolysis [54]. 1,3,5-Triazine carboxylates can be found as intermediates or side-products [55].

Alkylation with Alkyl Halides. Cyanamide salts can be dialkylated, especially with allyl and benzyl chlorides in water or alcohol at 60 °C [56].

$$2\,CH_2{=}CHCH_2Cl + NaHNCN + NaOH \rightarrow (CH_2{=}CHCH_2)_2NCN + 2\,NaCl + H_2O$$

Contrary to alkylations, cyanamide reacts upon silylations and stannylations as the carbodiimide tautomer. Bis-trimethylsilylcarbodiimide can be made from hexamethyldisilazane [57]. It is a versatile reagent to convert carbonyl functions to *N*-cyanoimines.

Acylation. Cyanamide can be acylated by reaction with carboxylic esters, acid chlorides, or anhydrides. The resulting *N*-cyanoamides are relatively strong acids that are best isolated as alkali metal salts [58]. Starting from alkyl chloroformates or dialkyl carbonates, alkoxycarbonylcyanamides are formed [59, 60]. Methoxycarbonylcyanamide is used to produce the benzimidazole fungicide Carbendazime [61].

N-Cyanoimines. The reaction of orthoesters, imidates, or amidines with cyanamide gives compounds such as *N*-cyanoimidates or *N*-cyanoamidines [62, 63]. These compounds are useful intermediates for the synthesis of 2-amino-1,3,5-triazines. Dimethyl-*N*-cyanimidocarbonate [64] (accessible from dimethylimidocarbonate) and dimethyl-*N*-cyanoimidodithiocarbonate [65] (from CS_2, cyanamide, and a methylating agent) are convenient starting materials for *N′*,*N″*-disubstituted *N*-cyanoguanidines such as Cimetidine or Tiotidine [66 – 68].

N-Heterocycles. A vast variety of *N*-heterocycles like imidazoles, 1,2,4-triazoles,

tetrazoles, pyrimidines and triazines can be made from cyanamide, often via isolable intermediates like guanidines, isourea compounds, or *N*-cyanoimines. Typical reactions are the synthesis of 2-aminoimidazoles [69, 70], 3-amino-1,2,4-triazole [71], 5-aminotetrazole [72], 2-aminopyrimidines [73], 2-halogenopyrimidines [74], 2-amino-1,3,5-triazines [62, 75], and 3-amino-1,2,4-benzotriazine-1-oxides [76].

2.3. Production

Cyanamide is manufactured from calcium cyanamide by continuous carbonation in an aqueous medium [77].

$$CaNCN + H_2O + CO_2 \rightarrow NH_2CN + CaCO_3$$

The following reactions take place:

$$2\,CaCN_2 + 2\,H_2O \rightarrow Ca(NHCN)_2 + Ca(OH)_2$$

$$Ca(OH)_2 + 2\,CO_2 \rightarrow Ca(HCO_3)_2 \rightarrow CaCO_3 + H_2O + CO_2$$

$$Ca(HNCN)_2 + CO_2 + H_2O \rightarrow 2\,NH_2CN + CaCO_3$$

In the continuous cyanamide process, the amount of calcium cyanamide and water added is equivalent to the aqueous cyanamide removed (Fig. 4) [78].

A carbonated slurry of cyanamide solution, solid calcium carbonate, and graphite is cooled to remove the heat of reaction (d). Part of the slurry is recycled to facilitate temperature control; the remainder is filtered, yielding a cyanamide solution and a cake of calcium carbonate and graphite. The final concentration of cyanamide is normally 25 %.

The calcium cyanamide feed is well mixed with the recycled slurry and filtrate in a feed vessel (b) and added at a rate to maintain a pH of 6.0 – 6.5 in the cooling tank. After carbonation, the slurry is held at 30 – 40 °C to complete the formation of calcium carbonate. The equipment is preferably stainless steel. This process is somewhat modified to produce a commercial 50 % solution and recover crystalline cyanamide. Calcium and iron are removed by ion exchange, if desired. Alternatively, the cyanamide solution can be further purified by membrane filtration [79].

Figure 4. Continuous manufacture of cyanamide and dicyandiamide from calcium cyanamide

Commercial Forms. The two main producers of cyanamide are Degussa AG in Trostberg Germany and Nippon Carbide in Japan. Both offer two grades:

1) Cyanamide in 50 % aqueous solution (trade names Cyanamid L500 and NC Cy-50), a clear slightly yellowish solution that can change reversibly to blue under the influence of light.
   Specifications:

Cyanamide	50 ± 1 %
Dicyandiamide and related compounds	max. 5 %
Iron	max. 500 mg/L
Calcium	max. 300 mg/L
Stabilizer	max. 2 %

The maximum storage life is 3 months if stored cool (below 20 °C) and under controlled conditions. It is shipped in polyethylene cans or drums up to 200 liters or as bulk

in specialized ISO containers equipped with a pressure relief system.

2) Pure, crystalline cyanamide (trade names Cyanamid F1000 and NC Cy-100): colorless crystals that are slightly hygroscopic and tend to cake under pressure.
Specifications:

Cyanamide	min. 99 %
Dicyandiamide	max. 1 %
Water	max. 1 %

The storage life is at least 3 months at temperatures below 20°C. The product is packed in steel drums with polyethylene inliners. The packaging size is limited to 50 kg.

2.4. Analysis

Cyanamide is determined by potentiometric titration with silver nitrate in ammoniacal medium [80]. It can also be determined by precipitation as the silver salt in ammoniacal solution and back-titration of the excess of silver ions [81] or by determination of nitrogen in the silver cyanamide precipitate [82]. Cyanamide can also be determined by direct HPLC with UV detection at 200 nm [83].

Traces of cyanamide can be analyzed spectrophotometrically after derivatization with pentacyanoammineferrate(II) [84]. Due to its low UV absorption, direct HPLC determination is not generally suitable. However, after derivatization with 1,2-naphthoquinone-4-sulfonate or with acetic anhydride, it can be detected by HPLC [85].

Dicyandiamide, the main impurity in cyanamide is routinely determined by reverse-phase HPLC (see Section 3.4).

2.5. Storage and Transportation

The commercial 50 % solution produced by Degussa AG is stabilized by a special buffer system to a pH between 4.0 and 4.6. Typically, it contains less than 1.5 % dicyandiamide, less than 0.5 % urea, and less than 0.1 % thiourea. This solution is stable for at least 3 months if stored at a temperature below 20 °C. Prolonged storage leads to an increase in the pH and thus to instability of the solution. If a pH of 5.2 has been reached, the product should be used quickly, above pH 5.5 it should be discarded immediately by mixing it with at least the double volume of water. Otherwise, a thermal runaway reaction leading to temperatures above 100 °C and potential bursting of the container may occur.

Aequous cyanamide solutions can be stored in stainless steel (e.g. DIN 1.4541, AISI 321 or DIN1.4571, AISI 316Ti), glass or glass-lined vessels, polyethylene, polypropylene, or poly(vinyl chloride) containers. Iron, copper, zinc, and brass unsuitable for storing cyanamide.

The commercial crystalline Cyanamide F1000 from Degussa AG contains a special stabilizer system to ensure safe handling and transportation. It can be stored at least for 3 months at or below 20 °C. Temperatures above 40 °C must be avoided in any case.

The following actions should never be done with commercial cyanamide: Addition of strong acids, addition of bases or basic substances, evaporation of aqueous cyanamide solution, recrystallization or distillation of cyanamide.

According to the valid regulations on transport of dangerous goods, a stabilized 50 % aqueous cyanamide solution is classified in class 8 (corrosive substances), UN number 2922, packaging group III, hazard label 8 and 6.1. As far as bulk containers are used for transport, the designated tanks (24 m^3) must be thermally insulated and equipped with a pressure relief system. Two bursting disks are required, with a diameter of 25 cm each, responding at an overpressure level of 6 bars. In addition, the maximum filling temperature must not exceed 18°C [86]. Cyanamide solutions shipped in drums of up to 200 liters do not require special precautions.

2.6. Uses

Due to its unique structure and reactivity, cyanamide has found very widespread application in many different areas like agrochemicals, pharmaceuticals, and specialty and industrial chemistry.

Agrochemistry. Cyanamide is used as a plant growth regulator and budbreaking agent (Dormex) to compensate for the lack of frost and to improve the budbreak of grapes and other fruit crops in areas with mild winters [87].

Cyanamide has a significant fungicidal and herbicidal potential [88] and is used in pig farming to overcome sanitary problems related with the pig manure. Because of rapid degradation, cyanamide does not cause any residue problems, but contributes to the overall nitrogen supply of the crops.

Cyanamide is the key raw material for many herbicides, fungicides, and insecticides. It is used to produce the herbicides Amitrol [71] and Hexazinone [89] and builds up the pyrimidine or 1,3,5-triazine subunit for a vast number of sulfonylurea herbicides like Bensulfuron or Metsulfuron methyl [90, 91]. The benzimidazole fungicides Carbendazim and Benomyl and the pyrimidine fungicides Cyprodinil, Pyrimethanil, and Mepanipyrim [92, 93] are based on cyanamide, as well as the pyrimidine insecticides Bupyrimate and Dimethirimol [94, 95] and neonicotinoids like Acetamiprid [96].

Many fungicidal and biocidal guanidine and biguanide compounds like Dodine [97], Guazatine and Iminooctadine [98] are based on cyanamide chemistry.

Pharmaceuticals. Cyanamide is the key raw material for the anti-ulcer drug Cimetidine [99]. The majority of antiviral and anticancer drugs with pyrimidine or purine structures are based on cyanamide and guanidine chemistry.

Some new anticancer drugs like Gleevec [100] and TMC-125 [101] exhibit an aminopyrimidine core derived from cyanamide.

The antihypertonic Minoxidil [102] has now found a second application as a hair growth stimulant. The 2-aminobenzimidazole unit in anthelmintics for human and veterinary application, such as Albendazole, Flubendazole, and Mebendazole [103], is derived from cyanamide. Fattyl alkyl guanidine salts are used in cosmetics for hair repair [104].

Industrial Chemistry. Cyanamide reacts with hydrogen peroxide to activate the peroxide bond. This has been used to improve bleaching of cellulosic pulp and textiles [37, 105 – 108]. Cyanamide salts of lead and zinc are potent corrosion inhibitors that are used for metal coatings [109]. Cyanamide is used to modify dyes for higher fiber reactivity [110]. In polymers, cyanamide has been used to cure epoxy resins [111] and to modify polyurethane dispersions [112, 113].

2.7. Legal Aspects

Cyanamide is listed in global inventories of existing chemicals, e.g., EINECS (European Union), TSCA Inventory (United States), DSL (Canada), AICS (Australia), IECSC (China) and MITI (Japan). Within the European Union, the chemical substance cyanamide , i.e., the solid compound, is classified as toxic (danger symbol T) and must be labeled with R21 (harmful in contact with skin), R25 (toxic if swallowed), R36/38 (irritating to eyes and skin) and R43 (may cause sensitization upon skin contact).

Following specific legal EU definitions, a 50 % aqueous cyanamide solution is to be considered as a preparation that was examined per se for acute oral toxicity (see Chapter 5). Consequently, this preparation has to be classified as harmful (danger symbol X_n) and R22 (harmful if swallowed) instead of R25. The other R phrases mentioned above are applicable for 50 % cyanamide solutions too. In Germany, cyanamide is classified in water hazard class 2 (hazardous for waters).

3. Dicyandiamide

The dimer of cyanamide is known as dicyandiamide or cyanoguanidine. The occurrence of dimerization on evaporation of an aqueous solution was known as early as 1851; the product was later named param (from paracyanamide). The name dicyandiamide was coined in 1862 [114] and, together with the abbreviation *dicy*, is now firmly established. The name dicyandiamide is not as descriptive as the name cyanoguanidine, which is preferred by Chemical Abstracts; however, the former is used in this article.

Raman spectra support the cyanoguanidine structure (**1**) [115]; the crystalline form apparently has the tautomeric form (**2**) [116].

Tautomerism undoubtedly exists between two or more forms of dicyandiamide. The preferred formulation appears to be tautomer **2**.

Dicyandiamide has achieved industrial importance as an intermediate for the production of guanidine salts (→ Guanidine and Derivatives), guanamines, and formerly melamine (→ Melamine and Guanamines).

3.1. Physical Properties [6]

Dicyandiamide [*461-58-5*], M_r 84.084, is an odorless, colorless, nonvolatile powder with a monoclinic prismatic crystal structure [117]. Solubilities are shown in Table 1 and Figure 5A; some other physical properties follow:

Melting point	210 – 212 °C
Crystal density	1.404 g/cm^3
Enthalpy of formation at 25 °C	+18.4 kJ/mol
Dissociation constants	
pK_a	14.8
pK_b	14.4

In some solvent mixtures, especially with strong hydrogen bonding capacity, dicyandiamide exhibits a high cosolvent effect with increased solubility (Fig. 5/>B).

3.2. Chemical Properties

Dicyandiamide reacts with a variety of reagents. It is the simplest organic compound containing the C−N, C=N, and C≡N groupings. Reaction may occur at one or more of these sites. The literature on the chemistry of dicyandiamide is extensive, and many more reactions than those indicated below have been reported.

Formation. Dicyandiamide is formed from ammonium dicyanoamide, equivalent to the Woehler urea synthesis [118].

Decomposition Reactions. Dicyandiamide is thermally stable up to about 170 °C, above which decomposition reactions occur that become violent around the melting point. Therefore, the measured melting point strongly depends on the heating rate. Decomposition products are melamine, ammonia, and higher condensed triazines like melam, melem, and melone [119].

Salt Formation. Dicyandiamide is amphoteric and forms salts with organic and inorganic acids and with alkali in an anhydrous medium. In very concentrated aqueous acid, the corresponding salt precipitates. Such salts are almost completely hydrolyzed in dilute solution.

With alkali and alkaline earth metal hydroxides, dicyandiamide forms salts [120], which are stable in concentrated aqueous solutions but hydrolyze in dilute solutions. The sodium salt is 94.5 % hydrolyzed in 0.1 M solution.

Hydrolysis. At elevated temperature in the presence of an equivalent amount of a mineral acid, dicyandiamide yields guanylurea salts. This reaction is quantitative and can be used as a basis for the determination of dicyandiamide [121]:

At atmospheric pressure and moderate temperature in the presence of aqueous ammonia, reaction of dicyandiamide with hydrogen sulfide gives guanylthiourea. With increased pressure, an additional atom of sulfur may be introduced to yield dithiobiuret [122]. Unlike dicyandiamide, guanylurea is basic and readily forms salts with organic and inorganic acids.

The reaction of dicyandiamide with concentrated sulfuric acid or glacial acetic acid containing a small amount of water yields guanidine and ammonium salts instead of guany-

Figure 5. A) Solubility of dicyandiamide in various solvents (g/100 g solvent); B) Solubilities of dicyandiamide (dicy) in some solvent mixtures (g/100 g solvent, solvent ratio by weight)

Table 1. Solubility of dicyandiamide in various solvents (g/100 g solvent)

Temperature	−33	0	10	20	30	40	50	60	80	100

Methane		2.8	3.1	3.8	4.5	5.7	7.4			

lurea. Treatment of dicyandiamide with nitric acid gives nitroguanylurea [123].

The imino group of dicyandiamide is hydrolyzed by barium hydroxide to give cyanourea [*2208-89-1*].

Reaction with Amines. Heating dicyandiamide with aromatic amines in water in the presence of an equivalent amount of mineral acid gives high yields of aryl biguanide salts [124].

R = aryl

Yields of biguanide salts from the reaction of dicyandiamide with ammonium salts are poor. The biguanide obtained reacts further with the ammonium salt, and the product forms the guanidine salt. This reaction is used for the commercial preparation of guanidine nitrate [*506-93-4*] [125]:

Reaction with Formaldehyde. Treatment with formaldehyde [126] produces resinous compositions of varying properties (→ Amino Resins) under acidic or alkaline conditions. The reaction can be controlled to give mainly the water-soluble hydroxymethyldicyandiamide, or carried further to yield amorphous, infusible solids.

Heterocyclic Compounds. Under pressure and in the presence of ammonia, dicyandiamide cyclizes to melamine, of which large amounts have been made in this manner. At present, however, melamine is produced primarily by the urea process [127].

Excellent yields of guanamines are obtained when dicyandiamide is heated with alkyl or aryl nitriles in the presence of a small amount of alkali [128].

In some cases, carboxylic esters can be treated with dicyandiamide in the presence of an alcohol and a metal salt to form substituted 1,3,5-triazines [129].

Reaction with urea affords ammeline [*645-92-1*].

Dicyandiamide reacts with a wide variety of compounds to yield substituted pyrimidines. Acetoacetic ester reacts with dicyandiamide in the presence of sodium ethoxide and ethanol to give 2-cyanoamino-4-hydroxy-6-methylpyrimidine [130]. Derivatives of barbituric acid are synthesized by condensation of dicyandiamide with disubstituted malonic or cyanoacetic acid; their ester, chloride, or nitrile derivatives yield cyaniminopyrimidines [131]. These can be alkylated in the 3-position and hydrolyzed to *N*-monoalkyl-5,5-disubstituted barbituric acids [123].

3.3. Production

Dicyandiamide is formed in almost quantitative yield by the dimerization of cyanamide in alkaline solution. The reaction occurs most readily at pH 8 – 10 by the addition of the anionic cyanamide species to the nitrile group. The product is a weaker acid than cyanamide; it is protonated immediately with the generation of a new cyanamide anion, which continues the process.

In the industrial production of dicyandiamide, cyanamide is first prepared from calcium cyanamide by continuous carbonation in an aqueous medium (see Chap. 2) at pH 7 – 8 and is then dimerized at pH 8 – 10.

$$CaNCN + H_2O + CO_2 \rightarrow H_2NCN + CaCO_3$$

$$2\,H_2NCN \rightarrow (NH_2)_2C{=}NCN$$

Figure 6. Effect of pH on rates of formation and decomposition of dicyandiamide

To obtain a clean product, dimerization is carried out after separation of the precipitated calcium carbonate and other insoluble matter such as graphite [132]. The filtered solution containing ca. 25 % cyanamide is adjusted to ca. pH 9 and held at ca. 80 °C for 2 h to effect the desired conversion. The resulting hot liquor is filtered and cooled in a vacuum crystallizer. The dicyandiamide crystals are centrifuged and transferred to a rotary drier. The pH of the reaction must be controlled. An increase in alkalinity accelerates decomposition by hydrolysis (Fig. 6).

The dried product is stored in bulk or packaged in multiwall bags.

3.4. Quality Specifications and Analysis

Dicyandiamide is determined by reverse-phase HPLC with water or water/methanol (99/1) as mobile phase and detection at 220 nm [133, 134]. Alternatively, thin layer chromatography on silica plates with acetonitrile/water/acetic acid (90/10/1) as mobile phase can be used. The dicyandiamide spots are visualized with elemental chlorine and potasssium iodide/starch [135]. After derivatization with 3-hydroxy-2-butanone, dicyandiamide can be analyzed by HPLC and detected at 260 nm [136]. For resin applications, the color of a solution of dicyandiamide in aqueous formaldehyde is determined, e.g,. according to the APHA scale.

A typical analysis of commercial dicyandiamide is:

Dicyandiamide	min. 99 %
Water	max. 0.2 %
Water insolubles	max. 0.1 %
Melting point	209 – 212 °C

Dicyandiamide is also sold in micronized form or as solution for special applications.

3.5. Storage and Transportation

Dry crystalline dicyandiamide is stable at normal temperatures. Dicyandiamide is stable in aqueous solution up to 80 °C; above 80 °C ammonia is liberated. Dicyandiamide is not hygroscopic, flammable, or corrosive.

Dicyandiamide is packed in paper bags of 25 kg net weight or in big bags of up to 1000 kg.

3.6. Uses

Dicyandiamide is an intermediate for a number of organic nitrogen compounds, such as guanamines, biguanides, and guanidine salts. Guanidine phosphate is used as a fire-retardant in water-based systems; guanamines are employed as copolymers in resin compositions. Melamine is used primarily as a cross-linking agent in coatings and laminates. Substituted biguanides, prepared from dicyandiamide and arylamines, are used as stabilizers and antioxidants for soaps and other fatty materials.

Dicyanamide condensates. The condensation of dicyandiamide with formaldehyde gives resins with broad industrial applications. The reaction can be controlled to give a water-soluble intermediate for impregnation of paper, wood, leather, and textiles [137]. These resins are effective as direct-dye fixing agents for textiles and leather products. Such agents allow dyeing and printing of fabrics with direct dyes, rather than with more expensive vat dyes. They also improve wash- and lightfastness. Dicyandiamide itself prevents odor formation in resin-treated fabrics.

Melamine resins can be flexibilized by modification with dicyandiamide, thus giving postforming properties to high-pressure laminates [138].

Dicyandiamide – formaldehyde condensates modified with cationic polyaminopolyamides have been used in paper manufacture [139]. Avoiding the use of formaldehyde, dicyandiamide can be condensed with polyamines with cleavage of ammonia. These condensates are used as textile auxiliaries [140].

Under certain conditions, formaldehyde and mixtures of dicyandiamide with casein or other proteins, urea, melamine, or aromatic amines give resinous compositions varying from white powders to creamy pastes or clear, glasslike products.

Dicyandiamide reduces the viscosity of certain colloidal solutions [141]. This property is commercially significant in the manufacture of glues and adhesives, in the coating and sizing of paper and textiles, and in the conditioning of phosphate drilling muds. This action could be useful in other applications requiring viscosity control.

Dicyandiamide fluidizes adhesives and glues that are based on converted starches, casein, α-protein (soya protein), and hide proteins or collagens, thus extending the useful life of the adhesive. Dicyandiamide is 2 – 5 times more effective than urea on the basis of weight.

Flame retardants. Dicyandiamide, in combination with phosphoric acid, is used as a flame-retardant for cellulosic materials [142]. It is used

commercially as a fire-retardant for wood, particularly shingles [143, 144].

Dicyandiamide is stable at room temperature and is used in coating formulations as a flame-retardant. When exposed to a flame, the coating composition bubbles up or intumesces to a foam that protects the substrate from ignition.

An intumescent formulation including dicyandiamide, pentaerythritol, monoammonium phosphate, titanium dioxide, latex binder, and water gives good foam volume at low coating weights with reasonable stability of the foam structure under ignition [145, 146].

Smoke- or gas-generating pyrotechnic compositions contain dicyandiamide as fuel with high nitrogen production. Such formulations are used for car air-bags [147] and for agrochemical fumigants [148].

Plastic additives. Dicyandiamide can be used as a component in copolymers and co-condensates [149]. It is used for the thermal stabilization of poly(vinyl chloride) (PVC), for which it is introduced in the solid form at 170 °C into the PVC melt or as an aqueous solution to a PVC emulsion [150]. It stabilizes cellulose and homopolymers and copolymers of formaldehyde.

Epoxy curing. A major industrial application for dicyandiamide is curing of epoxy resins. At temperatures above 180°C, it reacts in a highly exothermic, autocatalytic reaction to form a rigid polymer network. Although many mechanistic investigations are reported [151 – 154], the reaction pathways and the final structure of the cross-linked network is still uncertain. However, it is obvious, that dicyandiamide not only reacts at the two amino groups, but involves the cyano group reacting with α β-hydroxy group formed from the epoxy resin to form oxazolidinone ring structures [155]. The maximum cross-link density is obtained at a molar ratio dicyandiamide-to-epoxy near 1:7, which means to a hydrogen equivalent weight (HEW) for dicyandiamide of 12 g mol^{-1}.

For industrial applications, the curing temperature of pure dicyanamide/epoxy systems is generally too high. Therefore, accelerator compounds are used for most applications. Imidazole compounds like 2-*methylimidazole* [*693-98-1*] can decrease the curing temperature to 100–160°C depending on the accelerator amount and resin type, but signifcantly decrease the storage life of the resin mixture. *N′*,*N′*-Dimethyl-*N*-arylurea compounds (often called "urones") like Diuron [*330-54-1*] or 2,4-toluylene-bis(*N′*,*N′*-dimethylurea) [*17526-94-2*] are generally used as latent accelerator compounds providing low curing temperatures (120–160°C) combined with a long storage lifetime of the formulated material [155 – 157]. Amine adducts with, e.g., polyphenols are also used as latent accelerators [158].

Main industrial application fields for dicyandiamide-cured epoxy resins are in electro laminates (printed circuit boards), fiber-reinforced plastics (glass and carbon fiber composites, e.g., for ski equipment, tennis rackets, fishing rods, automotive and aerospace structural applications), heat-curable adhesives (mainly for structural bonding in the automotive and aerospace field) and decorative and functional powder coatings.

For printed circuit boards, dicyandiamide is generally used as a solution in various solvents, methyl cellosolve and dimethylformamide being preferred because of their good solubility properties (see Section 1.1). Imidazoles (usually 0.05 to 0.1 g per 100 g resin) are used as accelerators to catalyze the reaction with mainly brominated bisphenol A epoxy resins. Silane-coated glass fabrics are impregnated with the resin varnish, dried, and prereacted to form a prepreg. Those are pressed in several layers together with copper foil and cured at about 180°C [159] to form a rigid printed circuit board. It is known, that copper interferes with the dicy/epoxy reaction thus influencing adhesion and the polymer cross-link structure [160].

For composite materials and structural adhesives, dicyandiamide is used in a micronized form (particle size < 10 μm or below) in combination with urone-type accelerators [156, 157]. Typical formulations contain 100 parts of a standard liquid bisphenol A resin, 7 parts dicyanamide and 1 to 5 parts accelerator. The pasteous mixture is rolled onto fiber filaments or fabrics and prepregged by short period heating. The prepregs are pressed under vacuum and heat to form the specimen. Resins transfer molding is a newer development demanding for even smaller particle size dicyandiamide because of filtering effects.

Adhesives are based on the same resin/dicyanamide/accelerator mixtures, typically for-

mulated including mineral fillers and fumed silica to provide thixotropy. Such adhesives are mainly used for metal bonding, because dicyandiamide strongly increases adhesion to metals by altering the surface network structure [161].

For decorative powder coatings, dicyanamide/epoxy systems have lost some commercial significance in the past years, in favour of cheaper epoxy/polyester hybrids. However, functional coatings with high chemical resistance, good adhesion, and high corrosion resistance (e.g., for concrete rebar coating, pipe coating, and gas or water fittings) are mainly based on dicyandiamide-cured epoxy systems, often accelerated by imidazole/epoxy adducts.

Agriculture. Dicyanamide is used as a fertilizer additive to prolong the shelf life of nitrogen nutritients in soil [162 – 164]. This is based on the ability of dicyandiamide to inhibit the urease and nitrification activity of soil microorganisms [165].

Pharmaceuticals. Dicyandiamide is the raw material for antidiabetic biguanides like Metformin [*657-24-9*] and Phenformin [*114-86-3*], the antimalarial Proguanil [*500-92-5*], and the antiviral Moroxidine [*3731-59-7*].

3.7. Legal Aspects

Dicyandiamide is listed in global inventories of existing chemicals, e.g., EINECS (European Union), TSCA Inventory (United States), DSL (Canada), AICS (Australia), IECSC (China), and MITI (Japan). It does not need to be classified and labeled according to EU Directives on dangerous substances. In Germany, dicyandiamide is classified in water hazard class 1 (slightly hazardous for waters).

4. Substituted Cyanamides

Substituted cyanamides have found much less technical application. In general, they are not produced from cyanamide itself, but from cyanogen chloride by reaction with amines.

$$R_2NH + ClC{\equiv}N \rightarrow R_2NC{\equiv}N + HCl$$

Alkyl- and arylcyanamides are intermediates in the production of *N*,*N′*-disubstituted guanidines; arylcyanamides have been proposed as curable resins.

Dicyanamide is an instable, strongly acidic substance. The stable sodium dicyanamide [*1934-75-4*] is produced from cyanamide and cyanogen chloride on a commercial scale. It is used to produce biguanide disinfectants like PHMBG and Chlorhexidine [166]. It is also is a valuable reagent to synthesise certain 1,3,5-triazines [167, 168].

5. Toxicology and Occupational Health

The production of calcium cyanamide and cyanamide does not present any serious health hazard [169, 170]. However, exposure to these substances in combination with the consumption of alcoholic beverages may cause a vasomotor reaction known as cyanamide flush or mal rouge. Typical symptoms are hyperemia of the upper half of the body, tachycardia, dyspnoea, headache, and nausea [171]. Cyanamide inhibits the enzyme aldehyde dehydrogenase and thus interferes with the oxidation of alcohol. This results in the accumulation of acetaldehyde in the blood, an effect, which may account for these unpleasant, but transient symptoms.

Calcium Cyanamide. The acute oral LD_{50} of technical-grade calcium cyanamide is 765 mg/kg in rats [172] and 1800 mg/kg in mice [173]. The dermal LD_{50} (rabbit) is greater than 2000 mg/kg [173]. From a study on the acute inhalation toxicity (rat) it can be concluded that the 4-h LC_{50} of the technical-grade material is greater than 155 mg/m^3. No mortalities were observed at this maximum attainable concentration [172]. A single semi-occlusive application of calcium cyanamide (technical grade) to intact rabbit skin for 4 h elicited no dermal irritation [173]. Introduction of this test material into the rabbit eye produced severe ocular lesions [174]. A battery of mutagenicity tests (in vitro, in vivo) with technical-grade calcium cyanamide did not reveal indications for mutagenic activity [174]. According to a bioassay of calcium cyanamide for possible carcinogenicity, the test formulation was not carcinogenic for F344 rats or B6C3F1 mice of either sex [175].

Cyanamide. A comprehensive overview on the toxicity of cyanamide is given in [176]. The acute oral LD_{50} (rat) is 125 mg/kg. When applied dermally to rabbits, the LD_{50} was found to be 848 mg/kg. From an acute inhalation toxicity study in rats (4-h exposure) it appeared that the LC_{50} is greater than 1000 mg/m^3. No mortality or severe injury occurred at this highest possible concentration. All these values refer to the active ingredient cyanamide. The corresponding data for a 50 % aqueous solution are 300 mg/kg (acute oral LD_{50}, rat), 1700 mg/kg (acute dermal LD_{50}, rabbit) and $>$ 2000 mg/m^3 (LC_{50} inhalation, rat). Cyanamide (solid or 50 % aqueous solution) has distinct irritating properties to skin and eyes and is regarded as sensitizing in the guinea pig (Magnusson – Kligman method). Cyanamide did not show mutagenic effects in several experiments such as the Ames Test.

Dicyandiamide is essentially nontoxic [177]. The acute oral LD_{50} (rat) is higher than 10 000 mg/kg. In rabbits, the dermal LD_{50} is $>$ 2000 mg/kg. After inhalation of dust for 4 h, the LC_{50} in rats was greater than 259 mg/m^3. No mortality or signs of intoxication were seen at this maximum attainable concentration. The substance is not irritating to skin and eyes and does not have a sensitizing effect in the guinea pig. A battery of in vitro tests did not reveal mutagenic properties. The compound was not carcinogenic in an oral long-term study with rats. From human experience it appears that product dust may cause temporary mechanical eye irritation. An individual case of allergic contact dermatitis was observed in a worker employed in the production of flame retardants [178]. Patch tests with the dry powdered material on 200 human subjects did not indicate sensitizing or primary irritant effects [179].

Exposure Limits. Regarding the maximum allowable concentration at workplace, no such value has been set for dicyandiamide [177]. In the United States, recommended exposure limits are existing for calcium cyanamide (0.5 mg/m^3) and cyanamide (2 mg/m^3) [180]. The occupational exposure limit in Germany is 1 mg/m^3 for calcium cyanamide as well as for cyanamide [181].

3. **Production** 2
4. **Uses** 3
5. **References** 3

1. Introduction

Cyanates are salts of an acid having the empirical formula HNCO, M_r 43.03, which exists in two tautomeric forms [1 – 3]:

H−O−C≡N	⇄	H−N=C=O
Cyanic acid		Isocyanic acid
[*420-05-3*]		[*75-13-8*]

At ambient temperature, isocyanic acid clearly predominates. However, esters of both isomers exist, e.g., ethyl cyanate, C_2H_5OCN, and ethyl isocyanate, C_2H_5NCO. Isocyanic acid can be represented by three mesomeric structures:

Likewise, the anion of the inorganic salts is a resonance hybrid and may be derived from either tautomeric form of the acid.

Cyanate anion ↔ Isocyanate anion

Only sodium and potassium cyanate are manufactured commercially. There is no commercial interest in any other cyanate salt. Free cyanic acid HOCN is unstable and cannot be isolated.

2. Properties

In aqueous solution, sodium and potassium cyanate undergo hydrolysis according to Equations (1) and (2) [8].

$$OCN^- + 2\,H_2O \rightarrow CO_3^{2-} + NH_4^+ \quad (1)$$

$$OCN^- + NH_4^+ \rightarrow CO(NH_2)_2 \quad (2)$$

The rate of hydrolysis depends strongly on temperature, pH and concentration. In dilute strong acids, the reaction proceeds according to Equation (1). The reaction is rapid and complete within a short time. It is therefore used in the chemical analysis of cyanates. In concentrated hydrochloric acid, the trimerization product cyanuric acid can be observed as a byproduct. In alkaline solution, the rate of hydrolysis is very slow. Some cyanate decomposes with the formation of urea according to Equation (2).

The formation of cyanate ions is the first step in the detoxification of cyanide ions in water using hydrogen peroxide [9], followed by the further decomposition of the cyanate according to Equation (1) or (2).

In the dry state, cyanate salts decompose above 450 °C to form cyanides. The decomposition is influenced by certain metals. Both salts are hygroscopic, potassium cyanate much more so than sodium cyanate. When cyanate salts are heated to around 300 °C in moist air, they undergo hydrolysis to the corresponding carbonate with liberation of ammonia.

Sodium and potassium cyanate dissolve only in water. Solubility in organic solvents is very low. Some physical properties are listed in Table 1.

Table 1. Physical properties of sodium and potassium cyanate

	Sodium cyanate	Potassium cyanate
CAS registry number	[*917-61-3*]	[*590-28-3*]
M_r	65.01	81.12
mp, °C	550	315
ϱ, g/cm^3	1.893	2.056
Solubility (g/100 g solvent)		
in water	10.68 at 16 °C	75 at 25 °C
in ethanol	0.5 at *bp*	0.53 at *bp*
in benzene	0.13 at *bp*	0.18 at *bp*
in liquid ammonia	1.72 at − 19.8 °C 0.72 at 45 °C	1.70 at 25 °C

Both potassium and sodium cyanate are nonflammable. Strong irritation occurs when the dust is inhaled or gets into the eyes. According to transportation regulations, cyanates are not classified as dangerous goods.

3. Production

Sodium Cyanate, Technical-Grade. In production, sodium carbonate is used as sodium source [4]. Sodium hydroxide [5] is only useful for laboratory synthesis. Under production conditions, safety considerations make sodium hydroxide unpractical. Urea is the preferred source for the cyanate part of the molecule, giving rise to ammonium carbonate as byproduct. Sodium allophanate has been postulated as a possible reaction intermediate [6]. The appearance and disappearance of such an intermediate can be observed by HPLC analysis. The reaction equation is therefore postulated as follows (Eqs. 3 – 5).

$$H_2NCONH_2 \rightarrow NH_4^+OCN^- \quad (3)$$

$$Na_2CO_3 + NH_4^+OCN^- + H_2NCONH_2 \rightarrow NaOCN + NH_2CONHCOONa^+ + NH_3 + H_2O \quad (4)$$
